Nodular elastosis with cysts and comedones	394				

INTRODUCTION

Normal elastic tissue

Elastic fibers are the important resilient component of mammalian connective tissue, and their presence is necessary for the proper structure and function of the cardiovascular, pulmonary, and intestinal systems.^{1,2} Their structural role is to endow tissues with elastic recoil and resilience.³ They constitute less than 4% of the dry weight of the skin, forming a complex and extensive network in the dermis that imparts elasticity to the skin.⁴

Structure and composition

Mature elastic fibers are composed of structural glycoproteins, which contribute to the formation of 10- to 12-nm microfibrils, and elastin, a fibrous protein with a molecular weight of 72 kDa.⁴ Elastin forms an amorphous core to the elastic fibers, and this is surrounded by the microfibrils. Approximately 90% of the mature elastic fiber is elastin. It has a high concentration of alanine and valine but less hydroxyproline than is present in collagen. Elastin-producing cells secrete tropoelastin, a 70-kDa precursor of elastin, which becomes highly cross-linked by the action of lysyl oxidase to form mature elastin.⁵ It is the product of a single copy gene, located in the chromosomal locus 7q11.2, in the human genome.⁶ Mutations in this gene cause the Williams–Beuren syndrome and some cases of cutis laxa. The microfibrils consist of several distinct proteins, including fibrillin; abnormalities of the microfibrils occur in Marfan's syndrome (see p. 403). The fibrillin-1 gene (*FBN1*), identified in 1991, is located on chromosome 15q21.1.⁵ There is a second fibrillin gene on chromosome 5 (*FBN2*), mutations of which cause congenital contractural arachnodactyly.⁷

A new family of extracellular matrix proteins, the fibulins, is being characterized progressively. Fibulins 1–5 have been identified. The latter, fibulin-5, appears to be deficient in the autosomal recessive form of cutis laxa.^{8,9} Fibulin-5 is essential for dermal elastic fiber assembly.¹⁰ The various fibulins are localized to different parts of the elastic fiber, with fibulin-1 in the amorphous core and fibulin-2 in the fibrillin-containing elastin-associated microfibrils. Fibulin-2 is increased in solar elastosis.¹¹ Fibulin-4 is also essential for elastic-fiber formation because its absence abolishes normal elastogenesis and leads to irregular elastin aggregates.³ Its absence has also been found in a rare form of autosomal recessive cutis laxa.¹²

The papillary dermis contains fine fibers that run perpendicular to the dermoepidermal junction and connect the basal lamina to the underlying dermal elastic tissue.¹³ These oxytalan fibers, as they are called, consist of microfibrils without a core of elastin.¹⁴ They branch to form a horizontal plexus in the upper reticular dermis, where they are known as elaunin fibers. They contain a small amount of elastin. The mature elastic fibers with their full composition of elastin are found below this in the reticular dermis. These three types of fibers probably correspond to consecutive stages of normal elastogenesis.¹⁴

Formation of elastic fibers

The formation of elastic fibers by fibroblasts, and in some circumstances by smooth muscle cells and chondroblasts, entails several different steps that are still poorly understood. Theoretically, these stages would include the expression of genes coding for elastin polypeptides, various intracellular processes, secretion of the precursor components, and extracellular modifications leading to the assembly of the fibers.⁴ Fibulin-5 plays an important role in this assembly by acting as an adaptor molecule between elastin and the matrix scaffold.¹⁵

Elastin is secreted in the form of a precursor, tropoelastin. This is ultimately cross-linked with desmosine to form stable elastin.¹⁶ The

formation of desmosine requires the copper-dependent enzyme lysyl oxidase.¹⁶ Defects in this enzyme can result from a spectrum of mutations in the ATPase gene (*ATP7A*), as seen in Menkes' syndrome (see p. 401). Impaired elastinogenesis can also result from other altered transport mechanisms important to elastic fiber assembly.⁷ One such example is a deficiency in elastin-binding protein (EBP), which transports tropoelastin from its site of synthesis in the cell to the cell membrane. Costello syndrome (see p. 398) results from a functional deficiency in EBP.

A congenital disorder of glycosylation involving a defect in the biosynthesis of N- and O-glycans has been reported in several patients with cutis laxa, indicating the role these glycans play in the stability of various extracellular matrix proteins; they may be involved in the glycosylation of fibulin-5.¹⁷

Degrading of elastic tissue

Very few enzymes can degrade cross-linked elastin.¹⁸ One of these is elastase, which is found in the pancreas and in neutrophils, macrophages, platelets, certain bacteria, and cultured human fibroblasts.^{16,18} Elastases exhibit a broad specificity. They are found in all classes of proteinases. Elastase activity is present in neutrophil elastase, cathepsin G, proteinase 3, and matrix metalloproteinases (MMPs) 2 and 9 (gelatinases A and B).¹⁹ MMP-12 (matelloelastase) is another matrix metalloproteinase that also has an important role in the degradation of elastic fibers.³ The exact role of elastase in normal skin is uncertain; it plays a part in the elastolysis seen in anetoderma and in acquired cutis laxa associated with inflammatory skin lesions. Elastase inhibitors also exist; these include α_1 -antitrypsin, α_2 -macroglobulin, and lysozyme.²⁰ Two factors, vitronectin and delay-accelerating factor, appear to prevent damage to elastic fibers by complement.²¹ Further work is needed to clarify the role of these substances.

Age-related changes

There is evidence of continuing synthesis of elastic fibers throughout life, but after the age of 50 years the new fibers are loosely rather than closely assembled.²² With age, there is some loss of the superficial dermal fibers and a slow, progressive degradation of mature fibers.^{16,23} This is accompanied by changes in collagen and extracellular matrix.^{24,25} Ultrastructural changes include the formation of cystic spaces and lacunae, imparting a porous look to the fibers;^{26,27} they may fragment or develop a fuzzy, indistinct border.²⁶ The changes are quite distinct from those seen in solar elastosis.

Another age-related change is the deposition on elastic fibers of terminal complement complexes and vitronectin. This latter substance is a multifunctional glycoprotein that is hypothetically involved in the prevention of tissue damage in proximity to local complement activation.²⁸

Staining of elastic tissue

Elastic tissue can be demonstrated in hematoxylin and eosin (H&E)-stained sections if appropriate modifications, as described by O'Brien, are made.²⁹ Notwithstanding this method, the commonly used stains for elastic tissue are the orcein, aldehyde–fuchsin, Verhoeff, and Weigert methods. However, the superficial fine elastic fibers do not stain with most of these methods, although they will with a modified orcein stain¹⁶ and the Luna stain, which incorporates aldehyde–fuchsin and Weigert's iron hematoxylin.³⁰ The Luna stain also demonstrates a fibrillary component in solar elastosis. Elastic fibers stain a brilliant purple against a pale lavender background with this stain.³⁰ Miller's modification of Weigert's resorcin–fuchsin has been suggested as the best method for demonstrating new elastic fibers.³¹

A monoclonal antibody, HB8, has been described as a stain for elastic fibers.³² It has no advantages over the modified orcein, Luna, or Miller stains.

Categorization of elastic tissue disorders

A simple classification of disorders of cutaneous elastic tissue divides them into those in which the elastic tissue is increased and those in which it is reduced.³³ The solar elastotic syndromes are best considered as a discrete group. Minor alterations in elastic tissue may occur in the various collagen disorders, in line with the observation that alterations in one component of the connective tissue matrix may influence the structure and function of others.³⁴ This group will not be considered in great detail here.

Although not categorized separately in this chapter, it should be remembered that elastic fibers are the most important structure to undergo transepidermal elimination. This can occur in elastosis perforans serpiginosa, perforating folliculitis, perforating pseudoxanthoma elasticum, solar elastosis, keratoacanthoma, healing wounds, and hypertrophic discoid lupus erythematosus.

The clinical and pathological features of the major disorders of elastic tissue are summarized in Table 12.1. The genetic abnormalities in the various disorders are listed in Table 12.2.

INCREASED ELASTIC TISSUE

Very little is known about the mechanisms that lead to an increase in dermal elastic tissue. In addition to the conditions to be considered here, a mild increase in elastic tissue has been reported in osteogenesis imperfecta,³⁵ chronic acidosis,³⁶ amyotrophic lateral sclerosis,³⁷ and some stages of radiation dermatitis.^{38,39} The solar elastotic syndromes are also characterized by increased elastic tissue, and they are considered after this section.

ELASTOMA (ELASTIC NEVUS)

Elastoma (elastic nevus, juvenile elastoma,⁴⁰ nevus elasticus, and connective tissue nevus of Lewandowsky type⁴¹) is a variant of connective tissue nevus (see p. 364) in which the predominant abnormality is an increase in dermal elastic tissue.⁴² The lesions may be solitary or multiple,^{40,43} and in the latter circumstance they are often associated with

Table 12.1 Summary of the major disorders of elastic tissue

Diagnosis	Clinical features	Pathology
Elastoma	Solitary or multiple; papules and disks; sometimes osteopoikilosis; linear variant reported	Increased, thick, branching elastic fibers
Linear focal elastosis	Palpable stria-like yellow lines; lumbosacral region	Numerous elongated wavy fibers, some with 'paintbrush' ends
Focal dermal elastosis	Late-onset, PXE-like lesions	Increase in normal elastic fibers; no PXE changes
Elastoderma	Localized lax, wrinkled skin	Increased, pleomorphic elastic tissue in upper dermis
Elastofibroma	Deep scapular region; older age	Proliferation of collagen and elastic tissue
Elastosis perforans serpiginosa	Hyperkeratotic papules on face and neck	Papillary accumulation and transepidermal elimination of elastic tissue
Pseudoxanthoma elasticum (PXE)	Yellowish papules and plaques; angioid streaks	Fragmented and calcified elastic fibers in mid dermis; may perforate
Elastic globes	Asymptomatic	Basophilic cytoid bodies in the upper dermis
Solar elastosis	Thickened, furrowed skin	Accumulation of curled basophilic elastic fibers and elastic masses in upper dermis
Nodular elastosis	Usually periorbital with cysts and comedones	Comedones and usually solar elastosis
Elastotic nodules of the ears	Asymptomatic papules on the ear	Clumped masses of elastotic material
Collagenous and elastotic plaques	Waxy, linear plaques at juncture of palmar and dorsal skin	Thick collagen, some perpendicular; admixed granular, elastotic material; basophilic elastotic masses
Erythema ab igne	Follows repeated heat exposure	Elastotic material in dermis
Nevus anelasticus (papular elastorrhexis)	Papular lesions on lower trunk; early onset, no inflammation	A 'minus nevus' with reduced, fragmented elastic tissue in reticular dermis
Perifollicular elastolysis	Common; face and back; often associated acne vulgaris	Loss of elastic tissue around follicles
Anetoderma	Well-circumscribed areas of soft, wrinkled skin; may have preceding inflammation or be secondary to some other disease	Loss of elastic fibers, particularly in mid dermis
Papillary dermal elastolysis (fibroelastolytic papulosis)	Papules and cobblestone plaques on neck and upper trunk, resembling PXE	Loss of elastic tissue in papillary dermis; no calcification of remaining fibers
Mid-dermal elastolysis	Widespread patches of fine wrinkling; additional perifollicular papules in some cases; may have preceding inflammatory phase	Loss of elastic tissue from mid dermis
Cutis laxa	Widespread, large folds of pendulous skin; often involves internal organs; congenital or acquired	Fragmentation and loss of elastic fibers
Menkes' syndrome	Copper storage disease; brittle, 'steel wool' hair; vascular and neurological changes	Pili torti, often with monilethrix and trichorrhexis nodosa
'Granulomatous slack skin'	Pendulous skin in flexural areas; T-cell lymphoma	Lymphoid cells; granulomas with multinucleate giant cells; absence of elastic fibers

Table 12.2 Genetic abnormalities in disorders of elastic tissue	
Disease	Genetic abnormality (mutations unless stated)
Buschke–Ollendorff syndrome (elastomas)	Loss-of-function mutations in <i>LEMD3</i> (<i>MAN1</i>) on chromosome 12q14
Pseudoxanthoma elasticum	<i>ABCC6</i> gene on chromosome 16p13.1
Cutis laxa (dominant)	<i>ELN</i> (elastin) gene on chromosome 7q11.2
Williams–Beuren syndrome	Deletion of <i>ELN</i> and contiguous genes on chromosome 7q11.2
Cutis laxa (recessive)	<i>FBLN5</i> (fibulin-5) gene on chromosome 14 <i>FBLN4</i> (fibulin-4) gene Disorders of glycosylation
Cutis laxa (X-linked recessive)	Allelic to Menkes’ syndrome (see below)
Cutis laxa (acquired)	<i>FBLN5</i> and <i>ELN</i> mutations may predispose to some cases
Costello syndrome	Unknown; functional deficiency of elastin-binding protein <i>HRAS</i> gene on chromosome 11p15.5
Mid-dermal elastolysis	One family with Keutel syndrome had this change. Defect in <i>MGP</i> (matrix Gla protein) gene
Wrinkly skin syndrome	Deletions of 2q32 reported, but not subsequently accepted; defect in N-protein glycosylation likely
Marfan’s syndrome	Fibrillin-1 (<i>FBN1</i>) gene of 15q21.1
Menkes’ syndrome	<i>ATP7A</i> gene on chromosome Xq12–q13
Fragile X syndrome	<i>FMR1</i> gene on chromosome Xq27.3

multiple small foci of sclerosis of bone (osteopoikilosis). This association is known as the Buschke–Ollendorff syndrome^{44,45} and the cutaneous lesions as dermatofibrosis lenticularis disseminata. In several instances, the cutaneous lesions have shown abnormalities in collagen rather than elastic tissue (collagenomas),^{46–48} and for this reason dermatofibrosis lenticularis disseminata is not entirely synonymous with the term ‘elastoma’.⁴³

The Buschke–Ollendorff syndrome (OMIM 166700) is inherited as an autosomal dominant trait with variable expressivity.⁴⁴ Whereas most individuals with this syndrome have both skin manifestations and osteopoikilosis, some family members have only cutaneous lesions or only bony lesions, but not both.^{46,49–52} Bilateral cutaneous syndactyly has been reported in the syndrome.⁵³ The genetic defect in the Buschke–Ollendorff syndrome has now been determined. It involves loss-of-function mutations in the *LEMD3* gene (also called *MAN1*), which encodes an inner nuclear membrane protein that influences Smad signaling.^{54,55} Melorheostosis (OMIM 155950) appears to be allelic with this syndrome, and the concurrence of the two diseases has been reported.^{55–57} However, there has been a report of a father and son with both nevus elasticus and osteopoikilosis in which no *LEMD3* mutation was found.⁵⁸ This result suggests that there may be genetic heterogeneity in Buschke–Ollendorff syndrome. The condition known as papular elastorrhexis, considered by some to be a form of nevus anelasticus, has also been shown not to have *LEMD3* mutations.⁵⁹ The cutaneous lesions (elastomas) may be widely distributed flesh-colored or yellowish papules or localized, asymmetrically distributed plaques on the lower trunk or extremities.⁶⁰ These localized lesions are thought to represent type 2 segmental manifestations of an autosomal dominant trait.⁶¹ A large, multilobulated, exophytic variant has been reported.⁶² They develop at an early age. The nail–patella

Figure 12.1 Elastoma. (A) There is increased elastic tissue in much of the dermis but excluding either end. (Orcein) (B) There are coarse irregular clumps of elastic tissue within the reticular dermis. (Verhoeff–van Gieson)

syndrome, another disorder of connective tissue, has been reported in a family with the Buschke–Ollendorff syndrome.⁶³

Studies of the desmosine content of elastomas indicate a three- to sevenfold increase in elastin.⁶⁴ There appears to be an abnormality of elastogenesis with faulty aggregation of elastin units associated with the overall increase in elastin.

Histopathology

Examination of H&E-stained sections usually shows a normal dermis,⁴⁴ although sometimes there is an increase in its thickness. The epidermis may have a slight wavy pattern. Elastic tissue stains show an accumulation of broad, branching and interlacing elastic fibers in the mid and lower dermis (Fig. 12.1).⁴⁷ The papillary dermis is unaffected. Sometimes the elastic fibers encase the collagen in a marble-vein configuration.^{40,65} Clumped elastic fibers have been reported;⁶⁶ they are a regular feature in linear focal elastosis.⁶⁷ A morphometric analysis shows a four or fivefold increase in elastic fibers compared to normal skin; the diameter of the fibers is also increased.⁶⁸

Uncommon changes include an increase in acid mucopolysaccharides,⁴⁷ slight thickening of collagen bundles, or a well-developed vascular component.⁶⁹ Two cases have been reported with facial plaques and increased dermal elastic tissue;^{70,71} in one, there was also perifollicular mucin.⁷¹

Electron microscopy

Ultrastructural findings have been variable.^{64,72} Usually, there are branched elastic fibers of variable diameter, without fragmentation. Elastic microfibrils may be replaced by granular or lucent material.^{40,73} Collagen fibers are sometimes increased in diameter,⁷² and some fibroblasts may have dilated rough endoplasmic reticulum.⁶⁴ In linear focal elastosis, sequential maturation of elastic fibers can be seen, suggesting active elastogenesis.⁷⁴

LINEAR FOCAL ELASTOSIS

Linear focal elastosis (elastotic striae) is a distinctive acquired lesion composed of palpable, stria-like, yellow lines that typically occur in the lumbosacral region,^{67,74–80} but other sites, such as the face⁸¹ and legs,⁸² may be affected. There is a predilection for males. It occurs at all ages but predominantly in the elderly.⁸³ This condition, which has been likened to a keloid of elastic fibers, may be an unusual form of striae distensae (see p. 368),^{78,84} and similarly to striae distensae, a triggering factor may be a growth spurt.⁸⁵ However, its pathogenesis is currently unknown.⁸³ A family history (brother and sister) has recently been reported.⁸⁶

Histopathology

Numerous elongated, wavy elastic fibers are present in the mid dermis. At their ends, some fibers are split into a ‘paintbrush formation’.⁷⁷ Fragmented fibers are also present. The elastic fibers have been reported as thickened⁷⁸ or thinned. Clumped elastic fibers are sometimes seen.⁸³

FOCAL DERMAL ELASTOSIS

Focal dermal elastosis is a distinct entity of late onset, characterized by a pseudoxanthoma elasticum-like eruption.^{87–90} The elastin content of the skin is significantly increased.⁹¹

Histopathology

There is an increase in normal-appearing elastic fibers in the mid and deep dermis.⁸⁷ There are no changes of pseudoxanthoma elasticum.

ELASTODERMA

Elastoderma, an exceedingly rare condition, is an acquired, localized laxity of skin resembling cutis laxa with lax, extensible, wrinkled skin.^{92–94} The lesions are not indurated. Although usually acquired, a familial case (sisters) with lesions primarily in acral locations has been reported.⁹⁵ The clinical presentation therefore differs from elastoma (elastic nevus).

Histopathology

Elastoderma has an excessive accumulation of pleomorphic elastic tissue within the dermis, particularly the upper dermis. On routine H&E sections, there are numerous eosinophilic irregular fibers in the papillary and reticular dermis. On elastic tissue stains, there are masses of thin, intertwined fibers.⁹² The fibers are not calcified.^{94,96}

ELASTOFIBROMA

Elastofibroma (elastofibroma dorsi) is a relatively rare, slowly growing proliferation of collagen and abnormal elastic fibers with a predilection for the subscapular fascia of older individuals, particularly females.^{90,97–100} It is rarely found at other sites. Unusual locations include the hard palate mucosa¹⁰¹ and the external auditory canal.¹⁰²

Most elastofibromas are unilateral and typically asymptomatic, although bilateral examples have been described,^{103,104} and progressive pain and a snapping sensation on throwing have been described in young baseball pitchers with this lesion.¹⁰⁵ Multiple elastofibromas are rare.¹⁰⁶ Nearly two-thirds of the 300 or more cases so far reported have been from southern Japan.¹⁰⁷ Although an association with pseudoxanthoma elasticum has been recorded, there is no abnormality in the *ABCC6* gene.¹⁰⁸ The pathogenesis is unknown, but they may represent a reaction to prolonged mechanical stress, possibly involving disturbed elastic fibrillogenesis by periosteal-derived cells.¹⁰⁹ Cytogenetic studies have found evidence of chromosomal instability and/or clonal changes suggesting a neoplastic process.¹¹⁰ Elastofibromas are gray-white or tan in color and measure 5–10 cm in diameter. Subclinical elastofibromas have been found at autopsy.¹¹¹

Histopathology

Elastofibromas are nonencapsulated lesions that blend with the surrounding fat and connective tissue.⁹⁸ They are hypocellular and composed of swollen collagen bundles admixed with numerous, irregular, lightly eosinophilic fibers and some mature fat (Fig. 12.2). The fibers, which account for almost 50% of the tissue, stain black with the Verhoeff elastic stain. Some fibers are branched, whereas others show a serrated edge.

The elastic fibers contain elastin but not fibrillin-1. No staining for actin or desmin was observed in one study.¹⁰⁸ The cells express CD34.¹¹⁰ Clusterin, an apoprotein that functions similarly to small heat shock proteins, surrounds the abnormal elastic fibers in this lesion.¹¹²

The characteristic altered elastic fibers can be recognized on fine needle aspiration cytology.¹¹³

Electron microscopy

Electron microscopy confirms the presence of abnormal elastic fibers, which result from a proliferation of elastic fibrils around the original elastic fibers.¹¹¹ Large (‘active’) fibroblasts⁹⁷ and cells with the features of myofibroblasts¹¹⁴ have both been described.

ELASTOSIS PERFORANS SERPIGINOSA

Elastosis perforans serpiginosa (also known as perforating elastosis; OMIM 130100) presents as small papules, either grouped or in a circinate or serpiginous arrangement, on the neck, upper extremities, upper trunk, or face.^{115–121} Rarely, the lesions are generalized.^{90,122,123} There is a predilection for males, with the onset usually in the second decade. Familial cases have been reported.^{124–126} An autosomal dominant mode of inheritance with variable expressivity of the trait has been suggested.¹²⁷ In up to one-third of cases, there is an associated systemic condition or connective tissue disorder: these include Down syndrome,^{123,128–131} osteogenesis imperfecta,¹³² cutis laxa,¹³³ Ehlers–Danlos syndrome, Marfan’s syndrome, acrogeria, scleroderma,^{134,135} an abnormal 47,XXY karyotype,¹³⁶ diabetes mellitus,¹³⁷ perforating folliculitis,¹³⁸ and chronic renal failure.¹³⁹ An association with Behçet’s disease has been described.¹⁴⁰

Similar cutaneous lesions have been reported in patients with Wilson’s disease and cystinuria receiving long-term penicillamine therapy.^{133,141–145} In these patients, a local copper depletion or a direct effect of penicillamine on elastin synthesis may be responsible for the formation of the abnormal elastic fibers, which are then eliminated transepidermally.^{141,146} Elastic tissue damage appears to occur in areas of skin not affected by elastosis perforans serpiginosa¹⁴⁷ and in other organs as well – a feature generally lacking in the usual idiopathic form of the disease.^{146,148} Coexistence of elastosis perforans serpiginosa and cutis laxa has been reported in a patient with Wilson’s disease receiving penicillamine therapy.¹⁴⁹ The nature of the defect in the idiopathic form is unknown, but it is possible that perforating elastosis is the final

Figure 12.2 Elastofibroma dorsi. (A) Coarse elastic fibers are admixed with collagen and adipose tissue. (B) The fibers have an irregular outline. (H&E) (C) An elastic tissue stain confirms the irregular outline. (Verhoeff–van Gieson)

common pathway for more than one abnormality of elastic fibers.^{116,150} This theory is compatible with the finding of a 67-kDa elastin receptor in keratinocytes immediately surrounding the elastic materials being eliminated in lesions of elastosis perforans serpiginosa.^{151,152} The elastin receptor may be involved in the interaction between keratinocytes and elastin.^{151,152}

Various therapies have been used, including liquid nitrogen cryotherapy, isotretinoin, imiquimod,¹⁵³ and the ‘pinhole method’ using the carbon dioxide laser.¹⁵⁴

Histopathology^{115–118}

In fully developed lesions, there is a localized area of hyperplastic epidermis, associated with a channel through which the basophilic nuclear debris and brightly eosinophilic fragmented elastic fibers are eliminated (Fig. 12.3). A keratinous plug usually overlies this channel, which may take the form of a dilated infundibular structure or a more oblique canal coursing through hyperplastic epidermis, follicular epithelium, or the acrosyringium (Figs. 12.4 and 12.5). When the canal is oblique, sections may only show a surface plug of keratinous debris

Figure 12.3 Elastosis perforans serpiginosa. Debris is entering a channel within the epidermis. (H&E)

Figure 12.4 (A) Elastosis perforans serpiginosa. (B) Debris and elastic fibers are being enveloped by a bulbous protrusion of the epidermis. (H&E)

Figure 12.5 Elastosis perforans serpiginosa. Another case with a less obvious epidermal channel. (H&E)

and a localized area of hyperplastic epidermis that in its lower portion forms a bulbous protrusion into the dermis. This appears to envelop an area of the papillary dermis containing basophilic debris and some refractile eosinophilic elastic fibers.

Elastic tissue stains show increased numbers of coarse elastic fibers in the papillary dermis. Some of these appear to overlap the basal epidermal cells. In the region of their transepidermal elimination, the elastic fibers lose their staining properties as they enter the canal and become brightly eosinophilic. They will stain with the Giemsa method. A few foreign body giant cells and inflammatory cells are often present in the dermis adjacent to the channel. In older lesions, there is focal dermal scarring and usually an absence of elastic fibers.

IgM, C3, and C4 were demonstrated on the abnormal elastic fibers in the papillary dermis in one of two cases studied by immunofluorescence.¹⁵⁵

In *penicillamine-related cases*, there is an increased number of thickened elastic fibers in the reticular dermis and less hyperplasia of elastic fibers in the papillary dermis, except in the areas of active transepidermal elimination.¹⁵⁶ The elastic fibers are irregular in outline with buds and serrations. This may be discerned in H&E-stained

Figure 12.6 (A) Elastosis perforans serpiginosa due to penicillamine therapy. (H&E) (B) The elastic fibers have a serrated appearance. (Verhoeff-van Gieson)

preparations, but it is well shown by elastic tissue stains (**Fig. 12.6**)¹⁵⁷ or in Epon-embedded thin sections stained with toluidine blue.¹⁴⁶

Electron microscopy

Ultrastructural examination of the dermis in penicillamine-related cases shows that the elastic fibers have a normal core and an irregular coat with thorn-like protrusions at regular intervals, the so-called 'lumpy bumpy' or 'bramble-bush' fibers.^{156–159} Collagen fibers are also abnormal with extreme variations in thickness.^{159,160} Electron microscopy of idiopathic cases has shown increased numbers of large elastic fibers that are convoluted and branching.¹⁶¹ Fine filaments, similar to those in embryonic elastic fibers, are present on the surface of the fibers.^{161,162}

Differential diagnosis

The microscopic findings on H&E-stained sections can closely resemble those of other transepidermal elimination disorders, particularly perforating folliculitis, Kyrle's disease, or those labeled acquired perforating dermatosis that are particularly associated with chronic renal

failure. Finding coarse, thickened elastic fibers within the zones showing transepidermal elimination points to the correct diagnosis. However, elastic fibers can occasionally be found among the elements undergoing elimination in these other conditions. Perforating pseudoxanthoma elasticum (PXE) has been described, but in contrast to elastosis perforans serpiginosa, the elastic fibers are short, gnarled, basophilic, and calcified; as a result, they can be readily recognized. The 'lumpy bumpy' elastic fiber changes in elastosis perforans serpiginosa due to penicillamine therapy are quite distinctive, although at times they may bear a microscopic resemblance to the fibers seen in elastofibroma dorsi.

PSEUDOXANTHOMA ELASTICUM

Pseudoxanthoma elasticum (OMIM 264800) is an inherited disorder of connective tissue in which calcification of elastic fibers occurs in certain areas of the skin, eyes, and cardiovascular system.^{163–168} Mutations in the *ABCC6* gene on chromosome 16p13.1 are responsible for this condition. More than 60 different mutations of this gene have been reported.^{169,170} Its incidence ranges from 1:70,000 to 1:100,000 live births.¹⁷¹ Skin changes are usually evident by the second decade and consist of closely set yellowish papules with a predilection for flexural creases, particularly in the neck and axillae and less commonly in the groins, periumbilical area, and the cubital and popliteal fossae.^{164–166,172,173} Oral lesions may occur.^{167,174} The skin becomes wrinkled and thickened and eventually may become lax and redundant, resembling cutis laxa.^{175–178} Mental (chin) creases are common.^{179,180} The calcium content of affected skin may be up to several hundred times normal.¹⁸¹ Calcification occurring in the breast may lead to problems in the interpretation of mammograms.¹⁸² Eye changes include angioid streaks and a degenerative choroidoretinitis that may lead to blindness. Angioid streaks can occur in the absence of pseudoxanthoma elasticum;¹⁸³ other disorders showing this change include Ehlers-Danlos syndrome, Paget's disease of bone, sickle cell anemia, thalassemia, and lead poisoning.¹⁸⁴ Calcification of elastic fibers in arteries and intimal and endocardial fibroelastosis develop. The vascular changes may lead to hypertension, sudden cardiac death,¹⁸⁵ cerebrovascular accidents, and gastrointestinal hemorrhage.^{186–188} Gastric bleeding may be increased in pregnancy, but most pregnancies in this condition are uncomplicated.¹⁸⁹ Cerebral white matter lesions compatible with vascular leucopathy have been found in pseudoxanthoma elasticum and actually prompted clinical and laboratory evaluations that led to the diagnosis in one case.¹⁹⁰

There is a recent report of a child with cutaneous pseudoxanthoma elasticum who lacked mutations in the *ABCC6* gene but was found to have a homozygous missense mutation involving the *ENPP1* gene, associated with the disorder known as generalized arterial calcification of infancy.¹⁹¹ Another study confirmed the development of features of pseudoxanthoma elasticum in patients with *ENPP1* mutations but also found *ABCC6* mutations in some patients with generalized arterial calcification of infancy, suggesting that mutations in these two genes may lead to similarly altered physiological pathways.¹⁹²

Pseudoxanthoma elasticum has been associated with hemochromatosis¹⁸⁴ and certain hemoglobinopathies such as β -thalassemia and sickle cell disease.^{171,193} Nephrolithiasis is another rare association.¹⁹⁴ Its occurrence is interesting because the *ABCC6* gene encodes a transmembrane transporter protein ABCC6 (MRP6), a member of the ATP-binding cassette (ABC) superfamily.¹⁹⁵ Presymptomatic mutation analysis of the *ABCC6* gene in members of families with pseudoxanthoma elasticum can provide important prognostic information.¹⁹⁶ One study showed a statistically significant association between the R39G mutation of *ABCC6* and three particular ophthalmologic manifestations of the disease: peau d'orange retinal change, angioid streaks, and choroidal neovascular membranes.¹⁹⁷ This protein is strongly expressed in the liver and kidney, with a possible role in phosphocalcic

metabolism.¹⁹⁴ Hyperphosphatasia has been reported in several cases.¹⁹⁸ The administration of vitamin D₃ results in further deposition of calcium salts.¹⁹⁹ Oral phosphate binders have been used in a small number of cases, with clinical improvement of skin lesions in half.²⁰⁰ Urinary glycosaminoglycan levels are elevated early in the disease.²⁰¹ Polymyositis and lupus erythematosus are other associations, possibly due to chance.^{202,203}

Characterization of the gene mutations responsible for this condition has led to a change in our understanding of its inheritance. Previously, it was believed that there were two variants with autosomal dominant inheritance and two with autosomal recessive inheritance. The clinical presentations and severity of these variants appeared to differ.^{204–207} It was acknowledged that the interpretation of the genetic studies that resulted in these views was made difficult by the limited phenotypic expression of the disease in some individuals.²⁰⁸ It is now believed that fewer than 2% of cases, if any, are autosomal dominant. In one study of 142 subjects, all cases were autosomal recessive in their mode of inheritance.²⁰⁹ Consanguinity was high. Homozygous patients had typical clinical appearances, including angioid streaks in the eye, although the severity of the disease varied.²⁰⁹ All 67 subjects who were heterozygous for the gene showed no cutaneous features of pseudoxanthoma elasticum, but few had skin biopsies.²⁰⁹ Heterozygotes may uncommonly experience severe ophthalmological complications.¹³⁸ Whether they may have cardiovascular complications remains to be determined. Another study showed histological changes in dermal elastic fibers in heterozygotes, but the authors still concluded that the relevance of performing a skin biopsy to detect heterozygous carriers remains to be determined.¹⁹⁵

A new classification system has been proposed by Plomp *et al.* based on existing clinical and histopathologic criteria but incorporating current knowledge about the *ABCC6* gene.²¹⁰ A summary of these criteria follows:

Major criteria

1. Skin
 - a. Yellow cutaneous papules in plaques in typical locations, or
 - b. Fragmentation, clumping, and calcification of elastic fibers on skin biopsy
2. Eye
 - a. Peau d'orange of retina, or
 - b. Angioid streaks
3. Genetics
 - a. Mutation of both alleles of the *ABCC6* gene, or
 - b. First-degree relative who meets diagnostic criteria for PXE

Minor criteria

1. Eye
 - a. One angioid streak shorter than one disk diameter, or
 - b. One or more 'comets' in the retina, or
 - c. One or more 'wing signs' in the retina
2. Genetics
 - a. Mutation of one allele of the *ABCC6* gene.

Using this scheme, definitive diagnosis requires two or more major criteria not within the same category (i.e., 1, 2, or 3). Probable diagnosis requires two major skin or two major eye criteria, or one major criterion and one or more minor criteria not belonging to the same category as the major criterion. Possible diagnosis requires the presence of a single major criterion or the presence of one or more minor criteria. If mutational analysis of *ABCC6* is negative or not available, other conditions such as sickle cell anemia, β -thalassemia, and a PXE-like phenotype with cutis laxa and multiple coagulation factor deficiency should be excluded.²¹⁰

Patients purported to have coexisting elastosis perforans serpiginosa and pseudoxanthoma elasticum have been reported; they are now

regarded as having perforating pseudoxanthoma elasticum.^{211–214} In such a case, associated with Moya Moya vasculopathy, amino acid substitutions were found in a region close to the *ABCC6* gene site.²¹⁴ Many of these patients have so-called 'acquired pseudoxanthoma elasticum' (see later).

The factors that lead to the calcification of initially normal elastic fibers in pseudoxanthoma elasticum are not known.²¹⁵ The role of *ABCC6* has not been delineated, and its substrate has not been identified.¹⁹⁵ Polyanionic material is deposited in association with the calcified material. Cultured fibroblasts from patients with this condition release a proteolytic substance, and it has been postulated that this may cause selective damage to elastin, leading to calcification.²¹⁶ Fibrillin appears to be abnormal in only isolated cases (unlike the findings in Marfan's syndrome).²¹⁷ Decreased deposition of fibrillin-2 has been reported in pseudoxanthoma elasticum.²¹⁸ These isolated findings have been replaced with a viewpoint that several structural proteins with an affinity for calcium (vitronectin, fibronectin, and bone sialoprotein) are increased in this condition and responsible for the calcification of the elastic fibers.¹⁹⁵ There is evidence that promoter polymorphisms associated with pseudoxanthoma elasticum may promote increased MMP-2 expression, contributing to the elevated proteolytic activity observed in these patients.²¹⁹

There has been one report of spontaneous resolution and repair of elastic tissue calcification.²²⁰ There is one report of the successful treatment of this condition with oral tocopherol acetate and ascorbic acid, both antioxidants.²²¹ It took 2 years of treatment for the papules to disappear.²²¹

Acquired pseudoxanthoma elasticum

Acquired pseudoxanthoma elasticum refers to an etiologically and clinically diverse group of patients with late onset of the disease, no family history, absence of vascular and retinal stigmata, and identical dermal histology.^{168,222,223} The term 'perforating calcific elastosis' has been suggested for some of these cases.^{224,225} Included in this group are individuals exposed to calcium salts, including farmers exposed to Norwegian saltpeter (calcium and ammonium nitrate),^{226,227} and obese, usually multiparous black women who develop reticulated and atrophic plaques and some discrete papules around the umbilicus^{213,224,228} or lower chest.²²⁹ Perforation is common in this latter group.²³⁰ A combination of periumbilical with periareolar perforating pseudoxanthoma elasticum has been described.²³¹ Patients with chronic renal failure on dialysis have also been reported with this acquired variant.^{222,232,233}

Pseudoxanthoma elasticum-like fibers have been found in other skin diseases in the absence of other signs of this disease^{234,235} and also as an acquired localized disorder.²³⁶ These changes have been seen particularly in disorders of the subcutis, such as lipodermatosclerosis, morphea profunda, erythema nodosum, but also in granuloma annulare, lichen sclerosus, tumefactive lipedema, and a basal cell carcinoma.^{234,235} Clinical and histopathologic evidence of pseudoxanthoma elasticum was found in three patients who underwent liver transplantation; genetic testing did not detect mutations in *ABCC6* in either the recipients or the donor livers in this study.²³⁷

Pseudo-pseudoxanthoma elasticum refers to the development of the systemic changes of pseudoxanthoma elasticum in patients on long-term penicillamine therapy for Wilson's disease. However, it has also been used for the cases referred to previously as acquired pseudoxanthoma elasticum.²³⁸ A spectrum of elastic tissue disorders, particularly elastosis perforans serpiginosa (discussed previously), occurs with penicillamine therapy.^{239,240}

Histopathology¹⁶⁶

There are short, curled, frayed, basophilic elastic fibers in the reticular dermis, particularly in the upper and mid parts (Figs. 12.7 and 12.8). The papillary dermis is spared except at sites of transepidermal elimination

Figure 12.7 (A) Pseudoxanthoma elasticum. (B) Note the short, curled elastic fibers in the reticular dermis. (C) They are basophilic. (H&E)

Figure 12.8 Pseudoxanthoma elasticum. The elastic fibers are short and curled. (Verhoeff–van Gieson)

(perforation). The elastic fibers in affected skin are stained black with the von Kossa method (Fig. 12.9). They stain with the Verhoeff method, and there is intense blue staining with phosphotungstic acid hematoxylin (PTAH). Calcinosis cutis²⁴¹ and osteoma cutis^{177,178} are rare complications. There is a good correlation between the severity of the clinical change and the histology.²⁰⁹

If perforation is present, there is a focal central erosion or tunnel with surrounding pseudoepitheliomatous hyperplasia or prominent acanthosis (Fig. 12.10). Basophilic elastic fibers are extruded through this defect. Sometimes foreign body giant cells, histiocytes, and a few chronic inflammatory cells are present when there is perforation or traumatic ulceration.^{242,243} The giant cells may then engulf some elastic fibers.

In the *acquired localized* forms, the changes can be found in the dermis and/or the septa of the subcutaneous fat.²³⁵

Electron microscopy

Calcification occurs initially in the central zones of the elastic fibers.²⁴⁴ There is also some calcification of intercellular spaces and occasionally also of collagen fibers; the latter change may be reversible.^{198,229} There is continuing elastogenesis with some normal elastic fibers.¹⁹⁸ Twisted collagen fibrils and thready material,²⁴⁵ which has been found to contain fibrinogen, collagenous protein, and glycoprotein, are also present.²⁴⁶ This indicates that the abnormality is not limited to the elastic fibers.

Differential diagnosis

The elastic tissue changes in pseudoxanthoma elasticum are quite distinctive, and the misshapen, calcified elastic fibers do not truly resemble those in, for example, either collagenous and elastotic plaques of the hands or elastosis perforans serpiginosa. As noted previously, however, fibers identical to those in pseudoxanthoma elasticum can be seen in a variety of conditions. Occasionally, they are found coincidentally and unexpectedly in biopsy specimens. The author has observed the changes in a lesion of necrobiosis lipoidica in a patient who later was found to have had the other stigmata of pseudoxanthoma elasticum. There have been several recent studies of pseudoxanthoma elasticum-like papillary dermal elastolysis. These lesions consist of flesh-colored to yellowish papules and plaques in symmetrical distribution over the neck and supraclavicular regions in women, but they lack the microscopic features of pseudoxanthoma elasticum, featuring instead loss or marked reduction of elastic fibers

Figure 12.9 Pseudoxanthoma elasticum. (A) Calcium salts are deposited on the abnormal elastic fibers. (von Kossa) (B) Larger deposits of dystrophic calcification may occur. (H&E)

in the papillary dermis with melanophages in the same distribution (see later).^{247,248}

ELASTIC GLOBES

Elastic globes are small basophilic bodies, found in the upper dermis of clinically normal skin, that stain positively for elastic fibers (Fig. 12.11). They are considered with the other dermal cytotoid bodies on page 444. Numerous elastic globes have been reported in a patient with epidermolysis bullosa whose skin was wrinkled²⁴⁹ and in a patient with the cartilage–hair hypoplasia syndrome whose skin was hyperextensible.²⁵⁰

Because the globes contain D-aspartyl residue-containing peptide, it has been postulated that they result from UV-induced skin damage.²⁵¹

SOLAR ELASTOTIC SYNDROMES

The term ‘solar elastosis’ refers to the accumulation of abnormal elastic tissue in the dermis in response to long-term sun exposure. Photoaging

Figure 12.10 (A) Perforating pseudoxanthoma elasticum. (B) The elastic fibers that are about to undergo transepithelial elimination are short, curled, and frayed. Clumped elastic fibers are also present. (Verhoeff–van Gieson)

is a process distinct from the changes taking place due to chronological aging, although photoaging does increase in severity with chronological aging.^{252–255} The effects of both are cumulative.²⁵⁶ A review of photoaging was published in 2007.²⁵⁷ Another review examining treatment options was published in 2008.²⁵⁸ The cosmetic effects of photodamage are assuming increasing importance in society. There are many different clinical patterns of solar elastosis, some of which form distinct clinicopathological entities.^{259,260} Other clinical patterns are histologically indistinguishable from one another, and they are usually grouped together under the umbrella term ‘solar elastosis’.

The following entities are regarded as solar elastotic syndromes:

- Solar elastosis
- Nodular elastosis with cysts and comedones
- Elastotic nodules of the ears
- Collagenous and elastotic plaques of the hands.

Colloid milium can also be regarded as a solar elastotic syndrome because it appears that the colloid substance derives, at least in major part, from elastic fibers through actinic degeneration.²⁶¹ Colloid degeneration (paracoloid, colloid milium-like solar elastosis) has overlapping features histologically with both colloid milium and solar elastosis. These topics are considered with the cutaneous deposits in Chapter 14 (pp. 439–443).

Figure 12.11 Elastic globes. (A) There are multiple, round, and ovoid deposits in the papillary dermis. Solar elastosis is also present. (H&E) (B) An elastic tissue stain of the same case. (Verhoeff–van Gieson)

Solar elastotic skin is more susceptible than normal skin to chronic infections with *Staphylococcus aureus* and several other bacteria. This results from a decline in the adaptive capabilities of the immune system.²⁶² Uncommonly, this results in a chronic suppurative process, variants of which have been reported as ‘coral reef granuloma’ and blastomycosis-like pyoderma (see p. 646). Actinic comedonal plaque, in which fibrous tissue and comedones are present with some residual elastosis at the periphery, can be the end-stage picture of this inflammatory process.

Another secondary change that may occur in sun-damaged skin is the formation of actinic granulomas in which there is a granulomatous response to solar elastotic material and its resorption by macrophages and giant cells (elastophagocytosis, elastoclasia).^{263,264} Actinic granulomas present clinically as one or more annular lesions with an atrophic center and an elevated border. They are considered with the granulomatous tissue reaction (see p. 212). Elastophagocytosis has also been reported in association with various inflammatory processes in sun-protected skin.²⁶⁵

Ultraviolet light is usually incriminated in the etiology of the degenerative changes.²⁶⁶ Human studies have demonstrated that small amounts of UVA or solar-simulated UV are capable of producing cutaneous photodamage.^{267,268} Long-term exposure to PUVA (psoralens

and ultraviolet A) is associated with persistent increases in actinic degeneration and pigmentary abnormalities on both sun-exposed and sun-protected sites.²⁶⁹ However, it has been suggested that infrared radiation may also contribute because changes characteristic of solar elastosis are seen in erythema ab igne.²⁷⁰ Although not usually regarded as one of the elastotic syndromes, this condition is considered in this section because of its similar histological appearances. Two further causes of heightened elastosis are cigarette smoking^{271–273} and photosensitivity resulting from the therapeutic use of hydroxyurea.²⁷⁴ The degree of aging in photoprotected skin correlates significantly with patient age and a history of cigarette smoking.²⁷⁵

SOLAR ELASTOSIS (ACTINIC ELASTOSIS)

The usual clinical appearance of solar elastosis is thickened, dry, coarsely wrinkled skin with loss of skin tone.²⁷⁶ Sometimes there is a yellowish hue. There may be some telangiectasia and pigmentary changes (poikilodermatous changes) in severe cases.^{277,278} The best recognized clinical variant is cutis rhomboidalis, in which there is thickened, deeply fissured skin on the back of the neck. Other clinical patterns include citrine skin,²⁷⁹ Dubreuilh’s and other elastomas,²⁸⁰ and solar elastotic bands of the forearm.^{281,282} Elastotic bands are characterized by cord-like plaques across the flexor surfaces of the forearms.²⁸³ The author has seen a similar but much milder phenomenon on the face of a colleague with severe solar damage. Bullous lesions are extremely rare.^{284,285}

The origin of the elastotic material has been the subject of much debate. It has been attributed to the degradation of collagen or elastic fibers or both.^{286,287} Alternatively, it has been suggested by others that the material results from the actinic stimulation of fibroblasts.²⁸⁸ More recent work indicates that the elastotic material is primarily derived from elastic fibers.^{289,290} The increased elastin appears to result from transcriptional activation of the elastin gene.^{291,292} In contrast, various studies have clearly shown that in unexposed skin, elastin content decreases with age (–44%) between 50 and 70 years of age. Interestingly, the elastin content of moderately sun-exposed areas does not change during aging, which may be the result of age-induced reduction and sun-dependent increase in elastin.²⁹³ In addition to the increased production of elastin in sun-exposed skin, there is reduced human leukocyte elastase activity, possibly a consequence of increased lysosome production that protects elastin from proteolysis.²⁹³ In contrast, neutrophil elastase is increased following experimental irradiation of sun-protected skin.²⁹⁴ Clusterin, a glycoprotein, is markedly increased in solar elastosis. Its role is not completely elucidated.²⁹⁵ A small amount of type I and VI collagen and procollagen type III are present, but the significance of this finding remains uncertain.²⁸⁹ DNA photo-damage and UV-generated reactive oxygen species are the initial molecular events that lead to most of the typical histological and clinical manifestations of chronic photodamage of the skin.²⁹⁶ Photoaging results in the accumulation of glycosaminoglycans on the elastotic material in the upper dermis and not between collagen and elastic fibers as in normal skin.^{297,298} Fibrillin is also increased.²⁹⁹ Collagen VII is reduced, and this may contribute to the formation of wrinkles by weakening the bond between the dermis and the epidermis.²⁹⁹ D-Aspartyl residues are increased in chronological and photo-induced aging.²⁵¹ MMP-7 and -12 are increased in photodamaged skin; they may contribute to remodeling of elastotic areas.^{300,301} Metalloproteinase-1 may be responsible for the degeneration and reduction in collagen.^{302–304} Fibulin-2, which belongs to a novel family of extracellular matrix protein, is significantly increased in actinically damaged skin.¹¹ Other consequences of photoaging are mutations in p53 and the partial loss of the ability of epidermal cells to differentiate normally.³⁰⁵ The changes are qualitatively quite different from those seen in chronological aging,^{306,307} contrary to the assertion of some.³⁰⁸

The extent of solar elastosis may also correlate with the nature of certain cutaneous neoplasms. For example, BRAF-mutated melanomas have been found to occur in younger age groups in areas of skin without marked solar elastosis, whereas melanomas without BRAF mutations are found in areas with high cumulative sun damage (prominent solar elastosis).³⁰⁹

Various therapies have been used in recent times to improve the clinical appearance of photoaged skin.²⁵⁸ One such technique, dermabrasion, produces clinical improvement by the synthesis of type I collagen.³¹⁰ Another technique, the prolonged application of topical tretinoin (retinoic acid), produces epidermal thickening,^{257,311–314} hypergranulosis, an increase in epidermal Langerhans cells,²⁶³ the deposition of collagen in the papillary dermis,³¹⁵ and, sometimes, an increase in fine elastic fibers in the papillary dermis.³¹⁶ Carbon dioxide laser resurfacing and the intradermal injection of cross-linked hyaluronic acid may also be used.^{258,317} These changes may result in an improved clinical appearance,^{318,319} although this has not occurred in all studies.³²⁰ Imiquimod, tacrolimus ointment, topical 5-aminolevulinic acid, and topical estrogen creams have all been used successfully in the treatment of photoaging.^{321–324} Over-the-counter preparations have had variable results.³²⁵ The prolonged use of sunscreens results in a significant reduction in the amount of solar elastosis and other harmful effects;^{326,327} it is the most cost-effective therapy.^{257,298}

Histopathology

In mild actinic damage, there is a proliferation of elastic fibers in the papillary dermis. These are normal or slightly increased in thickness. In established cases, the papillary and upper reticular dermis is replaced by accumulations of thickened, curled, and serpiginous fibers forming tangled masses that are basophilic in H&E-stained sections (Fig. 12.12).²² Sometimes there are amorphous masses of elastotic material in which the outline of fibers is lost except at the periphery. These masses are thought to form from the tangled fibers because transitions can be seen on electron microscopy. A thin grenz zone of normal-appearing collagen is present in the subepidermal zone.³²⁸ This may have lost its network of fine vertical fibers. Collagen is reduced in amount in the reticular dermis. Telangiectases may be seen.²⁹⁸ In a study of Korean skin with chronic photodamage, there was a gradual decrease in the number and size of dermal vessels over several decades of sun exposure.³²⁹ Transepidermal elimination of elastotic material can occur.³³⁰ This process is not uncommon

following cryotherapy to severely damaged skin, which seems to trigger it in some individuals (Fig. 12.13). The elastotic material stains black with the Verhoeff stain (Fig. 12.14). Sometimes the homogeneous deposits are less well stained. Melanocytes and Merkel cells are both increased in number.^{331,332}

Biopsies from individuals with chronic sunlight exposure, some of whom had persistent erythema, have been described as showing a 'perivenular histiocytic-lymphocytic infiltrate in which numerous mast cells, often in close apposition to fibroblasts, were observed': this condition has been termed '**chronic heliodermatitis**'.³³³ In normal-appearing sun-exposed skin, there are more mast cells, macrophages, CD4⁺, CD45RO⁺ T cells and CD1a⁺ dendritic cells than in sun-protected skin.³³⁴

Epidermal changes also occur in severely damaged skin. The stratum corneum may be compact and laminated or gelatinous; it sometimes contains vesicles full of proteinaceous material.³³⁵ In the malpighian layer, cell heterogeneity, vacuolization, and dysplasia may be found.³³⁵

Figure 12.13 Solar elastosis. Curled elastotic fibers are insinuating between basal keratinocytes. This represents the early stages of the transepidermal elimination of these damaged fibers. (H&E)

Figure 12.12 Solar elastosis with amorphous and fibrillary material in the upper dermis. (H&E)

Figure 12.14 Perforating solar elastosis. The elastic fibers being eliminated are thick, curled, and serpiginous in morphology. (Verhoeff–van Gieson)

In *bullous solar elastosis*, there is a well-defined, horizontally oriented cleft, lined by fibrin, in the middle of a dermis showing marked solar elastosis.²⁸⁵ Red cell extravasation in the region of the cleft is not uncommon.³³⁶

Electron microscopy

A spectrum of ultrastructural changes is found that parallels the clinical degree of damage.^{22,337,338} In mild cases, the elastic fibers in the papillary dermis are increased in number. The microfibrillar dense zones become irregular in outline, more electron dense, and many times larger. In severe cases, the elastin matrix becomes granular and develops lucent areas around the microfibrillar dense zones.²² Some fibers become disrupted and show a moth-eaten appearance or become transformed into finely granular bodies.²² Similar ultrastructural findings have been reported in chronic radiodermatitis.³³⁹ Deformed collagen fibers, of various diameters, are found in the papillary dermis.³⁴⁰ Following PUVA therapy, the elastic fiber changes include a breakdown of the microfibrils and subsequent fragmentation of the elastic fibers.³⁴¹ Melanocytes show degenerative changes with the development of large intracytoplasmic vacuoles.³³¹

Scanning electron microscopy of solar elastosis shows some normal fibers, some thick damaged cylindrical fibers, and large masses of markedly changed fibers, which probably correspond to the amorphous deposits seen in severe cases.³⁴²

NODULAR ELASTOSIS WITH CYSTS AND COMEDONES

The solar degenerative condition, nodular elastosis with cysts and comedones, is also known as the Favre–Racouchot syndrome.³⁴³ It occurs as thickened yellowish plaques studded with cysts and open comedones.^{344–346} It involves the head and neck, but particularly the skin around the eyes. Lesions may extend to the temporal and zygomatic areas. A case involving the shoulder region has been reported.³⁴⁷ Rare cases are unilateral.^{348,349} There is a predilection for older males who have a history of prolonged solar exposure. Smoking may act in conjunction with solar damage to potentiate the development of this condition.^{349–351} A case precipitated by radiation therapy and successfully treated with low-dose isotretinoin has been reported.³⁵² Another case of radiation therapy-induced Favre–Racouchot disease has recently been reported.³⁵³ Another case was provoked by ultraviolet (UVA1 and UVB) radiation.³⁵⁴ Successful treatment of the condition has been reported with a combination including superpulsed carbon dioxide laser followed by extraction of cysts and comedones.³⁵⁵

Histopathology^{244,245}

In addition to the marked solar elastosis, there are dilated follicles, small epidermal cysts, and comedones that contain keratinous debris in the lumen (Fig. 12.15). The sebaceous glands are often atrophic. A study of patients without much solar exposure showed multiple comedones without significant solar elastosis, suggesting that the two processes might be independent.³⁵⁶

ELASTOTIC NODULES OF THE EARS

Elastotic nodules are small, usually asymptomatic, pale papules and nodules found predominantly on the anterior crus of the antihelix in response to actinic damage.^{357–359} They are often bilateral. There is a marked predilection for elderly white males. Rare cases develop on the helix, where they may be painful, simulating chondrodermatitis nodularis helicis. They may be diagnosed clinically as basal cell carcinoma, amyloid, or even small gouty topi.

Figure 12.15 Nodular elastosis with cysts and comedones. Marked solar elastosis is accompanied by a small epidermal cyst. (H&E)

Figure 12.16 Elastotic nodule of the ear. (H&E)

Histopathology³⁵⁸

There is marked elastotic degeneration of the dermis with the formation of irregular, coarse elastotic fibers and larger clumped masses of elastotic material (Figs 12.16 and 12.17). These changes are best seen with the Verhoeff elastic stain. The overlying epidermis shows mild to moderate orthokeratosis and some irregular acanthosis. There is mild telangiectasia of vessels in the papillary dermis, and some new collagen is often present in this area.

COLLAGENOUS AND ELASTOTIC PLAQUES OF THE HANDS

Also known as ‘degenerative collagenous plaques of the hands’, ‘kera-toelastoidosis marginalis’, and ‘digital papular calcific elastosis’,³⁶⁰ collagenous and elastotic plaques of the hands is a slowly progressive, degenerative condition found predominantly in older males.^{361–364} There are waxy, linear plaques at the juncture of palmar and dorsal skin of the hands. The condition particularly involves the medial

Figure 12.17 (A and B) Elastotic nodule of the ear. Clumped masses of elastotic material can be seen. (A, H&E; B, Verhoeff–van Gieson)

aspect of the thumbs and the lateral (radial) aspect of the adjacent index finger. In this respect, the lesions resemble in part those seen in the genodermatosis acrokeratoelastoidosis (see p. 298).³⁶¹ Physical trauma of a repetitive nature and prolonged actinic exposure may play a role in the etiology of collagenous and elastotic plaques of the hand.^{363,365}

Histopathology

The most noticeable changes are in the dermis, where there are numerous thick collagen bundles having a haphazard arrangement, but with a proportion running perpendicular to the surface (**Fig. 12.18**).³⁶⁶ There is often a slight basophilic tint to the dermis; elastotic fibers can be seen in the lower papillary dermis and intimately admixed with the collagen bundles in the reticular dermis. Basophilic elastotic masses are found in the upper dermis.³⁶⁰ The dermis shows reduced cellularity with large areas devoid of fibroblasts.^{364,367} Sweat ducts may be mildly dilated in the mid dermis and compressed in other areas.

In elastic tissue stains, the elastotic material in the lower papillary dermis is confirmed (**Fig. 12.19**). In the reticular dermis, granular and

Figure 12.18 (A) Collagenous and elastotic plaque. (B) The collagen bundles in the upper dermis have a characteristic haphazard arrangement, with some bundles arranged vertically. Elastotic material is admixed. (H&E)

elastotic material can be seen in an intimate relationship within some of the larger collagen bundles.³⁶¹ In some cases, there are focal deposits of calcification in the dermis. The changes are distinct from those of solar elastosis.

The overlying epidermis may show mild hyperkeratosis and thickening of the granular layer. In some cases, there is slight acanthosis, whereas in others there may be loss of the rete pattern.

ERYTHEMA AB IGNE

Erythema ab igne refers to the development of persistent areas of reticular erythema, with or without pigmentation, at the sites of repeated exposure to heat, usually from open hearths.^{368,369} Other causes have included frequent hot bathing,³⁷⁰ using laptop computers placed on the thighs,^{371,372} heating pad,³⁷³ and automobile seat heaters.³⁷⁴ The lower legs are usually involved. Erythema ab igne is now seen only rarely.³⁷⁵ Keratoses and, rarely, squamous cell carcinomas may develop in lesions of long standing.^{376,377}

Histopathology^{368,378}

There is thinning of the epidermis with effacement of the rete ridges and some basal vacuolar changes. Areas of epithelial atypia, resembling

Figure 12.19 Collagenous and elastotic plaque. Elastic tissue is reduced between the thickened vertical collagen. There are curled fibers in the papillary dermis. (Verhoeff–van Gieson)

that seen in actinic keratoses, are sometimes present. There is usually prominent elastotic material in the mid dermis.³⁷⁹ A few large histiocytes may be present. A small amount of hemosiderin and melanin may be present in the upper dermis.³⁶⁸

DECREASED ELASTIC TISSUE

There are several distinct levels in the biosynthesis of elastic fibers at which errors can be introduced. These can lead to reduced production of elastic fibers or to the appearance of abnormal ones. Breakdown of fibers (elastolysis) is another mechanism that can lead to a reduction in the elastic tissue content of the dermis. This probably results from increased elastase activity.

The reduction in dermal elastic tissue can be generalized, as in cutis laxa, or localized, as in anetoderma and blepharochalasis. Cases with features intermediate between these two types or with fine wrinkling of the skin occur. Sometimes the reduction in elastic fibers is

subclinical or overshadowed by other features. This is the case in various granulomatous inflammatory disorders.

Skin atrophy, associated with a decrease in elastic fibers, has been reported at the site of thiocolchicoside injections.³⁸⁰

NEVUS ANELASTICUS (PAPULAR ELASTORRHEXIS)

Nevus anelasticus is the term suggested by Staricco and Mehregan⁶⁹ for several cases reported in the earlier literature characterized by an absence or definite reduction and/or fragmentation of elastic fibers in cutaneous lesions of early onset.³⁸¹ Further cases have been reported in which multiple papular lesions have developed, particularly on the trunk.^{381–384} The term **papular elastorrhexis** has been used for such cases; it has been regarded by some as a distinct variant of connective tissue nevus³⁸⁵ and not synonymous with nevus anelasticus. The author has been criticized for not separating cases of papular elastorrhexis from nevus anelasticus.³⁸⁶ However, a paper by Ryder and Antaya suggested that nevus anelasticus, papular elastorrhexis, and eruptive collagenoma are the same entity; their preference for a name for this composite entity was papular elastorrhexis.³⁸⁷ The lesions are not perifollicular in distribution. Separation from the non-inflammatory type of anetoderma may be difficult (see later).

Histopathology

Sections show a localized reduction in elastic fibers, with normal collagen,³⁸² although homogenized collagen in the reticular dermis has been described.^{59,388,389} The elastic fibers may show intense fragmentation in some cases.³⁸¹ Fibers in the papillary dermis may be normal. There is no inflammation in nevus anelasticus, but mild dermal inflammation has been reported in **papular elastorrhexis**.³⁹⁰ However, this is a tenuous feature to use in separating these conditions because various elastic tissue diseases may have (mild) inflammatory stages.

PERIFOLLICULAR ELASTOLYSIS

Perifollicular elastolysis is a not uncommon condition of the face and upper back in which 1- to 3-mm gray or white, finely wrinkled lesions develop in association with a central hair follicle.^{391,392} Balloon-like bulging of larger lesions may develop.³⁹¹ The disorder is significantly associated with acne vulgaris.^{392,393} In one report, an elastase-producing strain of *Staphylococcus epidermidis* was found in the hair follicles located within lesions.³⁹¹ An association has been described with the infrequently reported **atrophia maculosa varioliformis cutis**, a condition characterized by non-inflammatory linear or punctate atrophic scars that appear mainly over the cheeks and forehead.³⁹⁴

Histopathology³⁹¹

There is an almost complete loss of elastic fibers confined to the immediate vicinity of hair follicles (Fig. 12.20). There is no inflammation.

ANETODERMA

Anetoderma (macular atrophy) is a rare cutaneous disorder in which multiple, oval lesions with a wrinkled surface develop progressively over many years.^{395,396} Individual lesions may bulge outwards or be slightly depressed. They usually herniate inwards with fingertip pressure. There is a predilection for the upper trunk and upper arms, but the neck and thighs may also be involved. Facial involvement may lead to chalazodermia.³⁹⁵ Onset of the lesions is in late adolescence and early adult life. Childhood cases have been reported.³⁹⁷ Familial cases are quite rare.^{398–403}

Figure 12.20 Perifollicular elastolysis. There is absence of elastic tissue around the pilosebaceous follicle. A few thin fibers are present near the edge of the photomicrograph. (Verhoeff–van Gieson)

Figure 12.21 Anetoderma. There is a heavy infiltrate of lymphocytes in the mid dermis. Beneath this, the elastic fibers have almost completely disappeared. Five years after this biopsy was taken, the patient developed cutaneous lupus erythematosus. (Verhoeff–van Gieson)

The onset of lesions may be preceded by an inflammatory stage with erythematous macules and papules (Jadassohn–Pellizzari type), or there may be no identifiable precursor inflammatory lesions (Schweninger–Buzzi type).³⁹⁶ These two types have been classified as *primary anetodermas*. Because an inflammatory infiltrate may be present even in cases with no clinical inflammatory features, this classification is outdated.⁴⁰⁴ Patients with primary anetoderma frequently have at least one prothrombotic abnormality, the most common being the presence of antiphospholipid antibodies.^{404–407} A case has been reported of anetoderma accompanying homocysteinemia in a patient with anorexia nervosa. Hyperhomocysteinemia is a risk factor for occlusive vascular disease.⁴⁰⁸ *Secondary anetodermas*^{395,396} develop during the course of other diseases, such as syphilis, leprosy, accompanying follicular induction in molluscum contagiosum,⁴⁰⁹ sarcoidosis, Stevens–Johnson syndrome,⁴¹⁰ granuloma annulare,⁴¹¹ tuberculosis, varicella,⁴¹² HIV infection,^{413,414} folliculitis,⁴¹⁵ angular cheilitis,⁴¹⁶ Lyme disease,⁴¹⁷ acrodermatitis chronica atrophicans,³⁹⁵ lupus erythematosus,³⁹⁵ amyloidosis, lymphocytoma cutis,⁴¹⁸ cutaneous B-cell lymphoma,^{419,420} mycosis fungoides,⁴²¹ juvenile xanthogranuloma,^{422,423} and immunocytoma,⁴²⁴ or following penicillamine therapy⁴²⁵ or hepatitis B immunization.⁴²⁶ Involution of cutaneous marginal zone lymphoma lesions with formation of anetoderma has been described.⁴²⁷ Patches of anetoderma may develop in extremely premature infants,⁴²⁸ usually at the sites of attachment of gel electrocardiographic electrodes.^{429,430} In fact, monitoring leads are suspected to be the most common cause of anetoderma of prematurity; positioning of these leads to avoid prolonged pressure can be important in minimizing the risk of this complication.⁴³¹ Anetoderma-like changes have been reported in a patient with the clinical features of atrophoderma. The term ‘atrophoderma elastolytica discreta’ was used for these lesions.⁴³² The association with urticaria pigmentosa may be coincidental.⁴³³ Rarely, secondary anetoderma overlies a pilomatrixoma.^{434,435} The lesions of secondary anetoderma do not always correspond with those of the primary disease process.

A variety of ocular and skeletal defects have been reported in individuals with anetoderma. They have been chronicled in a review of the extensive European literature on this condition.³⁹⁵

Theoretically, anetoderma could result from increased degradation or reduced synthesis of elastic tissue.⁴³⁶ It has been suggested that all cases have an inflammatory pathogenesis, which would tend to indicate that an elastolytic process is operative.^{21,437} Increased expression of various

metalloproteinases has been reported; they play an important role in the degradation of elastic fibers in anetodermic skin.^{19,438} The concentration of elastin, as measured by the desmosine content of the skin, is markedly reduced.⁴³⁶ Immunological abnormalities, the most common of which is a positive antinuclear factor, have been documented.^{439–441}

Histopathology⁴³⁷

If a biopsy is taken from a clinically inflammatory lesion, the dermis will show a moderately heavy perivascular and even interstitial infiltrate, predominantly of lymphocytes. Plasma cells and eosinophils are occasionally present. Neutrophils have been noted sometimes in very early lesions.⁴³⁷

In established lesions, most reports have noted an essentially normal appearance in H&E-stained sections. However, in one large series, a perivascular infiltrate of lymphocytes was found in all cases.⁴³⁷ There was a predominance of helper T cells.⁴⁴² The authors of that account did not attempt to reconcile their findings with earlier reports in which inflammatory cells were noted to be absent.^{396,436,437}

Scattered macrophages and giant cells, some showing elastophagocytosis, may also be present.⁴⁴³ Noncaseating granulomas were present in one case, in association with Takayasu’s arteritis.⁴⁴⁴

Elastic tissue stains show a normal complement of fibers in the early inflammatory lesions. In established lesions, elastic fibers are sparse in the superficial dermis and almost completely absent in the mid dermis (Fig. 12.21).

Direct immunofluorescence in some cases of primary anetoderma shows a pattern of immune deposits similar to that of lupus erythematosus.⁴⁴⁵ There are no other manifestations of the latter disease in these cases.

Electron microscopy

The elastic fibers that remain are fragmented and irregular in appearance, but the collagen is normal.^{436,446} Occasionally, macrophages can be seen enveloping the fragmented fibers.⁴⁴⁷

CUTIS LAXA

The term ‘cutis laxa’ encompasses a group of rare disorders of elastic tissue in which the skin hangs in loose folds, giving the appearance of premature aging.^{390,448} In many cases, there is a more generalized loss

of elastic fibers involving the lungs, gastrointestinal tract, and aorta, leading to emphysema, hernias, diverticula, and aneurysms.⁴⁴⁹⁻⁴⁵² It is an etiologically heterogeneous disorder.

Congenital and acquired forms exist. *Congenital cutis laxa* is genetically heterogeneous. There are several different autosomal recessive forms of the disease. The first, autosomal recessive cutis laxa I (ARCL I; OMIM 219100), is potentially life-threatening, associated with pulmonary atelectasis, emphysema, multiple diverticula, hernias, and vessel abnormalities.⁴⁵³ The second, ARCL II, consists of a spectrum of disorders, including growth retardation,⁴⁵⁴⁻⁴⁵⁸ dysmorphism, and skeletal abnormalities. It overlaps with related disorders, including the De Barsy syndrome (OMIM 219150) (see later), *geroderma osteodysplastica* (OMIM 231070), and 'wrinkly skin' syndrome (OMIM 278250).⁴⁵³ There is an autosomal dominant form (OMIM 123700) that is less severe.⁴⁵⁹ One of the dominant forms is allelic to the Williams–Beuren syndrome and is related to mutations in the elastin (*ELN*) gene.⁴⁶⁰ The X-linked recessive variant (OMIM 304150),⁴⁶¹ in which there is a deficiency of lysyl oxidase, is now regarded as a variant of Menkes' syndrome (OMIM 309400);^{460,462,463} the two are allelic.⁴⁶⁰ It is caused by mutations in the *ATP7A* gene.⁴⁶⁴ The congenital forms are associated with a characteristic facies, with a hooked nose and a long upper lip ('bloodhound' facies).⁴⁶⁵ Congenital cutis laxa has been reported in a young male with the Kabuki makeup syndrome.^{466,467} It has also been reported in a newborn with congenital hypothyroidism due to isolated thyrotropin deficiency.⁴⁶⁸

More than 50 cases of *acquired cutis laxa* have been described. The changes may be generalized or localized.⁴⁶⁹⁻⁴⁷⁴ Localized cases may be acral or cephalic in distribution.⁴⁷⁵ Acquired cutis laxa may be of insidious onset⁴⁷⁶ or develop after a prior inflammatory lesion of the skin⁴⁷⁷ that may take the form of erythema, erythema multiforme, urticaria,^{478,479} a vesicular eruption, including dermatitis herpetiformis,⁴⁸⁰ or Sweet's syndrome.⁴⁸¹ Several cases have followed an allergic reaction to penicillin,^{482,483} whereas others have been associated with isoniazid therapy,⁴⁸⁴ mastocytosis,⁴⁸⁵ myelomatosis,⁴⁸⁶⁻⁴⁸⁹ multiple myeloma-associated amyloidosis (acrolocated cutis laxa),⁴⁹⁰ cutaneous lymphoma,^{491,492} rheumatoid arthritis,⁴⁹³ systemic lupus erythematosus,⁴⁹⁴ or the nephrotic syndrome.⁴⁴⁸ In a case associated with celiac disease, deposits of IgA were present on the dermal elastic fibers.⁴⁹⁵ Cutis laxa may occur as a manifestation of pseudoxanthoma elasticum. Late-onset cutis laxa also occurs in hereditary gelsolin amyloidosis (type V – familial amyloidosis of the Finnish type (OMIM 105120)) caused by a G654A or G654T *gelsolin* gene mutation on chromosome 9q34.^{496,497} Gelsolin amyloid is deposited in dermal nerves, blood vessels, and appendages, and it often encircles elastic fibers in the lower dermis leading to fragmentation and loss of fibers.⁴⁹⁸

The *congenital* cases result from a defect in the synthesis or assembly of the components of the elastic fiber. All patients with the autosomal dominant form of cutis laxa who have had genetic sequencing studies performed have had mutations in the *ELN* gene localized to chromosome 7q11.2.⁴⁹⁸ Its product, tropoelastin, is the most abundant component of elastic fibers.^{464,499} Mutations in the *ELN* gene not only cause cutis laxa⁴⁹⁹ but also cause subvalvular aortic stenosis,⁵⁰⁰ which may occur as an isolated disease or as part of the Williams–Beuren syndrome (Williams' syndrome), a microdeletional syndrome that involves the deletion of one complete copy of *ELN* (see later).^{464,501} The *De Barsy* syndrome appears to be another subgroup of cutis laxa that may involve a defect in elastin production with increased degradation.⁵⁰² This syndrome is also characterized by progeroid features and mental retardation.⁵⁰³

The molecular defects underlying the recessive forms of cutis laxa have been discovered.^{8,9} Mutations in the fibulin-5 gene (*FBLN5*) were the first identified;⁴⁶⁰ they are seen in ARCL I. Mutations in this gene are also responsible for age-related macular degeneration, the leading cause of irreversible visual loss in the Western world.⁵⁰⁴ A missense mutation in the fibulin-4 (*FBLN4*) gene has also resulted in cutis laxa.¹²

Mutations in the *ATP6-V0A2* gene are associated with ARCL II. This gene encodes the α_2 subunit of the vesicular H⁺ pump, and the mutation causes impaired vesicular trafficking, tropoelastin secretion, and cell survival.⁴⁵³ Mutations have also been found in the *PYCR1* gene (OMIM 179035), which encodes the enzyme pyrroline-5-carboxylate reductase-1.⁴⁵³ Manifestations of this variant include wrinkled skin, joint laxity, hip dislocation, and a progeroid appearance. A congenital disorder of glycosylation involving a defect in the biosynthesis of N- and O-glycans has also been found in patients with cutis laxa.¹⁷ Other rare syndromes associated with cutis laxa in which the mechanism of the decrease in fibers is not known include the Barber–Say syndrome (OMIM 209885), characterized by a dysmorphic face and hypertrichosis;⁵⁰⁵ the SCARF syndrome (OMIM 312830), with skeletal abnormalities;⁵⁰⁶ and geroderma osteodysplasticum (OMIM 231070).⁵⁰⁷ It has been suggested that the elastic tissue abnormality in geroderma osteodysplasticum has overlap features between cutis laxa and wrinkly skin syndrome (OMIM 278250).⁵⁰⁸ An excellent summary of the various types of cutis laxa and their defects is available.⁵⁰⁹

In *acquired* cases associated with severe dermal inflammation, it has been suggested that granulocytic elastase may be responsible for the degradation of the elastic fibers. Cultured fibroblasts from one case showed increased elastase activity.⁴⁷⁹ One report suggested that several factors, including high levels of cathepsin G, low lysyl oxidase activity, and a reduction in circulating proteinase inhibitor(s), could all contribute to the loss of elastin.⁵¹⁰ Collagenase and gelatinase A and B expression is upregulated at the transcriptional level in cutis laxa.⁵¹¹ This may explain the collagen abnormalities (see later) that are sometimes found.⁵¹² A more recent paper has described missense alleles in both the elastin and fibulin-5 genes in a patient with acquired cutis laxa with inflammatory destruction of elastic fibers, suggesting an underlying genetic susceptibility in some patients with acquired cutis laxa.⁵¹³

Localized areas of loose skin may develop in cutaneous lesions of sarcoidosis, syphilis, and neurofibromatosis.⁴⁷⁶ Loose skin localized to the hands, feet, and neck and also deep palmar and plantar creases are seen in **Costello syndrome** (OMIM 218040), in which there are also characteristic facies, mental retardation, growth disorders, and, sometimes, hypertrophic cardiomyopathy.⁵¹⁴⁻⁵¹⁶ Acanthosis nigricans may also be present.⁵¹⁷ There is an increased susceptibility to bladder cancers and rhabdomyosarcoma. It results from a functional deficiency in EBP.^{7,514} Mutations in the *HRAS* gene on chromosome 11p15.5 account for the majority of cases of Costello syndrome, but other candidate genes have been mentioned sporadically.

Reduced elastic fibers were present in one case of the 'Michelin tire' syndrome (see p. 1016).⁵¹⁸

Histopathology⁵¹⁹

The fine elastic fibers in the papillary dermis are lost, and there is a decrease in fibers elsewhere in the dermis (**Fig. 12.22**). Remaining fibers are often shortened, and they vary greatly in diameter. The borders are sometimes indistinct and hazy (**Fig. 12.23**). Fragmentation of fibers may be noted. Giant cells are rarely present, phagocytosing elastic fibers. A variable inflammatory reaction is present in the acquired cases with an associated clinical inflammatory component.⁴⁷⁸ In several cases, the inflammatory infiltrate has been quite heavy, with neutrophils, eosinophils, and lymphocytes in the superficial and deep dermis.⁴⁸³ Deposits of immunoglobulins have been demonstrated on elastic fibers in the dermis in several cases.^{489,495}

Shortening and rupture of elastic fibers are seen in Costello syndrome. There are decreased amounts of elastin.⁵¹⁵

Electron microscopy⁴⁴⁸

The elastic tissue varies in content, appearance, and the proportion and manner by which elastin and the microfibrillar component associate.^{520,521} The microfibrils are reduced in the papillary dermis.⁵²² There

Figure 12.22 (A) Cutis laxa. (B) There is an almost complete absence of elastic fibers. (Orcein)

Figure 12.23 Cutis laxa. Elastic fibers are shortened, vary in diameter, and have indistinct, hazy borders. (Verhoeff–van Gieson)

is some fragmentation of elastic fibers with accumulation of granular material.⁴⁸⁶ Fragmented fibers are sometimes surrounded by fibroblasts or macrophages. Abnormalities of collagen structure have been noted in a few reports^{520,523} but specifically excluded in others.⁴⁸⁶ An unusual case of acquired cutis laxa, associated with the cutaneous and systemic deposition of a fibrillar protein, has been reported.⁵²⁴

Differential diagnosis

Reduced or absent elastic fibers can be seen in other conditions, including anetoderma, miscellaneous inflammatory conditions featuring elastophagocytosis, papular elastorrhexis, and primary forms of elastolysis (see later). However, in none of those conditions do the remaining elastic fibers show the shortened contours and indistinct outlines characteristic of cutis laxa. Nevertheless, it has been noted that mild elastic tissue changes may be difficult to discern in biopsy specimens, even with traditional histochemical stains for elastic fibers. Therefore, the absence of obvious morphologic changes does not completely exclude the diagnosis of cutis laxa. Antibody staining for molecules known to be involved in cutis laxa will likely become the future diagnostic method of choice, at least for identifying specific forms of the disease.⁵⁰⁹

Elastolysis of the earlobes

Elastolysis of the earlobes may represent a variant of cutis laxa confined to the earlobes.⁵²⁵ This is supported by cases with associated facial involvement.^{479,525} **Blepharochalasis** is a similar condition that presents with recurrent bouts of painless edema of the eyelids and periorbital region resulting in degradation of elastic fibers and their subsequent loss from the dermis.^{494,526} The floppy eyelid syndrome is morphologically similar.⁵²⁷

WILLIAMS–BEUREN SYNDROME

Williams–Beuren syndrome (OMIM 194050), also known as Williams' syndrome, is a multisystem, congenital disorder characterized by craniofacial, neurobehavioral, cardiovascular, and metabolic changes.^{501,528} It results from a microdeletion in the q11.23 region of chromosome 7, involving the elastin gene and up to 26 other genes such as the *LIMK1* gene.⁵²⁹ It is therefore a contiguous gene syndrome. Genes on other chromosomes have also been implicated. Its prevalence is approximately 1 in 10,000 births. Despite a moderate reduction in elastin deposition in the skin, the clinical changes are relatively mild with increased softness and mobility of the skin.⁵²⁸

Histopathology

The overall appearance of the skin in H&E sections is normal. Morphometric analyses of elastic fibers have demonstrated a marked reduction in elastic fiber diameter and volume compared with healthy controls.⁶⁸

A study of 10 cases showed the presence of disorganized pre-elastic (oxytalan and elaunin) fibers in the papillary dermis and disorganized mature elastic fibers in the reticular dermis.⁵³⁰ Fibers were shortened and rarefied.⁵³⁰

PAPILLARY DERMAL ELASTOLYSIS (FIBROELASTOLYTIC PAPULOSIS)

Papillary dermal elastolysis is a rare disorder of elastic tissue characterized by clinical lesions resembling pseudoxanthoma elasticum, with small papules and cobblestone plaques on the neck and upper trunk.^{25,531} Reported cases have occurred exclusively in females, but if the merged entity (see later) is accepted, both sexes may be involved.⁵³² Similar histopathological changes were present in a case presenting as a small, hyperpigmented plaque.⁵³³ It has been suggested that this condition is part of the spectrum of white fibrous papulosis of the neck (see p. 365), for which the term 'fibroelastolytic papulosis of the neck' has been suggested.⁵³² The pathogenesis of these two merged entities is unknown; it is possibly related to intrinsic aging.^{532,534}

The coexistence of papillary dermal elastolysis and linear focal dermal elastosis in the same patient has been reported.⁵³⁵

Histopathology

There is a complete loss of elastic fibers in the papillary dermis (Fig. 12.24). The remaining fibers are not calcified or fragmented; that is, there are no histopathological features of pseudoxanthoma elasticum. Elastophagocytosis was present in one case, suggesting that this may be the mechanism for the loss of elastic fibers.⁵³⁶ Immunohistochemical studies have demonstrated a disappearance of both elastin and fibrillin-1 from the papillary dermis, suggesting that this condition is more than an age-related state.^{537,538}

Figure 12.24 Papillary dermal elastolysis. There is loss of elastic fibers in the papillary dermis. (Verhoeff–van Gieson)

MID-DERMAL ELASTOLYSIS

Mid-dermal elastolysis, first described by Shelley and Wood in 1977,⁵³⁹ is characterized by widespread patches of fine wrinkling due to a loss of elastic fibers from the mid dermis.^{539–544} The clinical features can be quite subtle.⁵⁴⁵ A few cases have shown a second clinical feature with looseness of the skin around hair follicles.⁵⁴⁶ Other cases have had flesh-colored papules in a perifollicular distribution.⁵⁴⁷ A third clinical pattern with a prominent reticular appearance has been reported.⁵⁴⁸ Presentation as erythematous, reticulated patches has also been described in two patients.⁵⁴⁹ It may represent the end stage of granuloma annulare.⁵⁴⁸ Most cases have involved the upper extremities, neck, and trunk of women. It may represent a variant of anetoderma.

In nearly 50% of cases, erythema, urticaria, or burning precedes or coincides with the development of the lesions, suggesting that an inflammatory process may be involved in the pathogenesis. In some cases, the condition appears to be photoinduced or photoaggravated.^{547,550,551} The onset has followed augmentation mammoplasty with silicone implants,⁵⁵² granuloma annulare,^{553,554} and lupus erythematosus.⁵⁵⁵ Lesions may remain stable for many years. Mid-dermal elastolysis has been reported in one family with the Keutel syndrome (OMIM 245150), a rare autosomal recessive syndrome characterized by abnormal cartilage calcification and due to mutations in the matrix Gla protein (*MGP*) gene.⁵⁵⁶

There is some similarity to the cases reported from South Africa and South America, in young children, in whom wrinkling developed after a preceding inflammatory stage.^{557–559}

An immunohistochemical study has shown enhanced expression of CD34⁺ and CD68⁺ cells and of MMP-1.⁵⁶⁰ A recent study has confirmed an increase in MMP-1 activity, followed by elastin degradation.⁵⁶¹ Another study confirmed the increase in CD68⁺ cells but found that MMP-9 was present in epidermal keratinocytes and in large cells in lesional dermis.⁵⁴⁷ This study of 11 patients concluded that the onset of the disease is strongly associated with UV exposure, which may induce fibroblast-like cells to express MMP-9 that in turn could be involved in the degradation of elastic fibers.⁵⁴⁷ In another study, MMP-9 was also implicated in the destruction of the elastic fibers in this condition.²²¹ In a study of one patient, there was not only upregulation of MMP-9 but also reduced expression of lysyl oxidase-like proteins, indicating altered elastin renewal in mid-dermal elastolysis lesions.⁵⁶²

Histopathology

Sections stained with H&E may appear normal, although in the early inflammatory stage a mild infiltrate of lymphocytes is present around vessels and, to a lesser extent, in interstitial areas.^{546,563} Spindle-shaped cells and large multinucleated cells with angulated outline are scattered between collagen bundles in the mid dermis in these early lesions.⁵⁴⁷ They did not stain for CD68 or factor XIIIa in one study.⁵⁴⁷ Phagocytosis of elastic fibers has been present in some cases^{543,564} but specifically excluded in others.^{546,550} This may, of course, be related to the age of the lesion biopsied. Two cases of mid-dermal elastophagocytosis, presenting as persistent reticulate erythema, have been reported.⁵⁶⁵ Of the two previously mentioned cases presenting as erythematous reticulated patches, both showed degrees of elastophagocytosis, with variable vasodilatation and lymphocytic or histiocytic dermal infiltrates.⁵⁴⁹

There is one report of a patient with mid-dermal elastolysis in which the initial erythematous and urticarial plaques revealed a neutrophilic infiltrate in the papillary and mid dermis and a normal pattern of elastic fibers.⁵⁶⁶ In addition to the neutrophils, there was leukocytoclastic debris; some endothelial swelling of vessels; and a few admixed lymphocytes, histiocytes, and eosinophils.⁵⁶⁶

Stains for elastic tissue show an absence of fibers in the mid dermis (Fig. 12.25). Elastic tissue is usually preserved around appendages, even in the clinical subset with perifollicular involvement.⁵⁶⁷ There is no involvement of the papillary dermis or the lower reticular dermis.⁵⁴⁶

With confocal laser scanning microscopy, papillary dermal vessels were more dilated than in normal skin, whereas with optical coherence tomography, there was a higher mid-dermal signal intensity in normal skin compared to that in lesional skin.⁵⁶⁸

Electron microscopy

Degeneration of elastic fibers has been recorded. Engulfment of elastic fibers by macrophages can be seen in cases that have histological evidence of elastophagocytosis.^{536,563}

MENKES' SYNDROME

Menkes' kinky hair syndrome (OMIM 309400) is a rare multisystem disorder of elastic tissue transmitted as an X-linked recessive trait.^{569–571} The defective gene (*ATP7A*) has been localized to chromosome Xq12–q13.^{572,573} Characteristically, the hair is white, sparse, brittle, and kinky. It looks and feels like steel wool. Pili torti and, occasionally, monilethrix are present. Neurodegenerative changes, vascular insufficiency,

Figure 12.25 Mid-dermal elastolysis. There is loss of elastic fibers in the mid dermis. (Verhoeff–van Gieson)

hypothermia, and susceptibility to infections are other manifestations of this syndrome.^{38,571} Mild forms occur.⁵⁷⁴

The finding of reduced serum copper levels led to the view that Menkes' syndrome was a simple copper deficiency state akin to that seen in copper-deficient sheep.^{575,576} It is now thought to be due to a spectrum of mutations in the copper-transporting ATPase gene, *ATP7A*.⁷ There is reduced activity of the copper-dependent enzyme lysyl oxidase in fibroblasts derived from the skin of patients with this syndrome.⁵⁷⁷ This enzyme is necessary for the cross-linking of elastin.⁴ It has been suggested that this syndrome should be reclassified with Ehlers–Danlos syndrome type IX, in which a disorder of lysyl oxidase also occurs (see p. 377).

Histopathology

There are various hair shaft abnormalities, including pili torti, monilethrix, and trichorrhexis nodosa.⁵⁷¹ The internal elastic lamina of vessels is fragmented, and there is intimal proliferation. Dermal elastic tissue appears to be unaffected.

Electron microscopy

The elastic fibers in the reticular dermis show a paucity of the central amorphous component while retaining normal microfibrillary material.⁵⁷²

FRAGILE X SYNDROME

Fragile X syndrome (OMIM 300624), a rare X-linked form of mental retardation, is associated with a characteristic facies and connective tissue abnormalities that are clinically reminiscent of cutis laxa and the Ehlers–Danlos syndromes.^{578,579} Most cases result from an increase in length of a stretch of CGG triplet repeats in the *FMR1* gene situated on the long arm of the X chromosome (Xq27.3).^{580–582} Rarely, the condition results from the deletion of all or part of this gene.^{581,583} Attention deficit hyperactivity disorder is a frequent behavioral problem in young boys with fragile X syndrome.⁵⁸⁴

Histopathology⁵⁷⁸

There is a reduction in dermal elastic tissue. The fibers are fragmented and curled, and they lack arborization. There is a reduction in stromal acid mucopolysaccharides.

WRINKLY SKIN SYNDROME

Wrinkly skin syndrome (OMIM 278250) is a rare autosomal recessive disorder characterized by wrinkled skin with poor elasticity over the abdomen and on the dorsum of the hands and feet.^{585,586} It has some features overlapping with cutis laxa type II.⁵⁸⁷ A recent study was unable to distinguish between wrinkly skin syndrome and cutis laxa with growth and developmental delay (OMIM 219200).⁵⁰⁸ Increased palmar and plantar creases, a prominent venous pattern on the chest, microcephaly, and musculoskeletal abnormalities form part of the syndrome. There is overlap between wrinkly skin syndrome and geroderma osteodysplasticum (OMIM 231070).^{508,588}

The genetic defect in this syndrome has not been characterized, but one case has been associated with deletion of 2q32.⁵⁸⁵ A defect in N-protein glycosylation seems to be the likely mechanism of this disease.⁵⁰⁸

Histopathology

There is an irregular pattern of elastic fiber distribution. Oxytalan fibers are absent from the papillary dermis. Thickened and fragmented fibers are present in the mid dermis, while there is a paucity of elastic fibers in the deep dermis; those present are in fragmented clumps.⁵⁸⁵

GRANULOMATOUS DISEASES

Rarely, anetoderma develops as a complication of sarcoidosis, leprosy, or tuberculosis. Reduced numbers of elastic fibers, not necessarily leading to clinical manifestations, may occur in the course of several other granulomatous disorders. These include the closely related conditions of elastolytic giant cell granuloma, actinic granuloma, atypical necrobiosis lipoidica of the face and scalp, and Miescher's granuloma.^{589,590} Elastic tissue is reduced in active lesions of granuloma annulare. Multinucleate giant cells and macrophages appear to be responsible for the digestion of the elastic fibers.⁵⁸⁹ These conditions are discussed further in Chapter 7 (pp. 189–218).

'GRANULOMATOUS SLACK SKIN'

Granulomatous slack skin, a rare form of cutaneous T-cell lymphoma, is characterized by progressively pendulous skin folds in flexural areas and an abnormal cutaneous infiltrate.^{591–596} A unique t(3;9)(q12;p24) translocation has been reported in one patient.⁵⁹⁷ The distinctive clinical appearance results from elastolysis, apparently mediated by giant cells in the infiltrate (see p. 1181).

Histopathology⁵³⁵

There is permeation of the entire dermis and subcutis by a heavy infiltrate of lymphocytes admixed with tuberculoid granulomas and giant cells with up to 30 nuclei. Foam cells may also be present.⁵⁹³ There is almost complete absence of elastic tissue in the dermis, and elastic fibers may be seen within the giant cells. Loss of elastic fibers and subcutaneous granulomas are not present in the granulomatous form of mycosis fungoides, which otherwise resembles this condition on histopathology (see p. 1177).⁵⁹¹

MYXEDEMA

Elastic fibers are significantly reduced in the dermis in hypothyroid myxedema and in pretibial myxedema.⁵⁹⁸ Ultrastructural examination shows wide variability of elastic fiber diameter and a decrease in microfibrils.⁵⁹⁸

ACROKERTOELASTOIDOSIS

Acrokeratoelastoidosis (OMIM 101850) is a genodermatosis (see p. 298) in which the dermal elastic fibers are usually fragmented and decreased in number. Sometimes they are normal.^{583,599} The epidermal changes are clinically more significant than the elastic tissue changes, although pathogenetically the elastorrhexis is probably the primary event and the accompanying keratoderma could be secondary to chronic trauma.^{600–604} The term focal acral hyperkeratosis has been proposed for a clinically identical disorder but in which changes in elastic fibers cannot be demonstrated.⁵⁹⁹

VARIABLE OR MINOR ELASTIC TISSUE CHANGES

LEPRECHAUNISM (DONOHUE SYNDROME)

Leprechaunism, also known as Donohue syndrome (OMIM 246200), is a rare disorder with characteristic facies, phallic enlargement, and a deficiency of subcutaneous fat stores.⁶⁰⁵ Cutaneous changes include

hypertrichosis, acanthosis nigricans, wrinkled loose skin, and prominent rugal folds around the body orifices.⁶⁰⁵

It is due to mutations in the insulin receptor gene on chromosome 19p13.2.

Histopathology

Loss and fragmentation of elastic fibers and decreased collagen were noted in one report of this condition.⁶⁰⁶ In contrast, in another study it was noted that the elastic fibers were thick and extended into the widened septa of the subcutaneous fat.⁶⁰⁵

SYNDROMES OF PREMATURE AGING

The elastic tissue changes in the premature aging conditions are variable. They may be increased in Werner's syndrome (see p. 378) with granular and filamentous ultrastructural changes.⁶⁰⁷ Elastosis perforans has been reported in acrogeria (see p. 379).⁶⁰⁸ At other times, there may be loss of elastic fibers in association with dermal atrophy or sclerosis.⁶⁰⁹

WRINKLES

Although of great cosmetic importance, wrinkles are of little dermatopathological interest. In general, wrinkles are bilateral and increased with aging and sun damage. One case of unilateral wrinkles has been reported.⁶¹⁰ Wrinkles are an important component of 'smoker's face', resulting from prolonged cigarette smoking.^{271,611–614} Wrinkles may result from a reduction in collagen VII in photodamaged skin, with a consequent weakening of the bond between the dermis and epidermis.²⁹⁹ Estrogen therapy appears to reduce the incidence of wrinkles.⁶¹⁵ The use of bovine collagen injections theoretically poses the risk of the transmission of bovine spongiform encephalopathy.⁶¹⁶

Histopathology^{617–620}

It has been stated that wrinkles are a 'configurational change' with no distinguishing histological features.⁶¹⁷ In contrast, it has been reported that the dermis in a deep wrinkle shows substantially fewer elastotic changes than the surrounding areas and that the superficial elastic fibers appear slightly thickened and the overlying epidermis depressed.^{619,620} Increased elastosis is found in biopsies from 'smoker's face'. It appears to result from degradation of existing fibers and not from the synthesis of new elastic material.⁶¹³

A study involving 157 skin biopsies demonstrated numerous modifications in different structures of the skin: hypertrophied elastotic tissue on the flanks of the wrinkle and reduced or absent elastic fibers under the wrinkle, atrophy of the dermal collagen under the wrinkle, and a marked decrease in chondroitin sulfates and oxytalan fibers in the papillary dermis.⁶²¹

Electron microscopy

Electron-dense inclusions have been noted in elastic fibers in the upper dermis of the wrinkled areas; these are thought to represent the earliest changes of solar elastosis.^{619,620} More severe changes are present in the surrounding dermis.

SCAR TISSUE

There have been conflicting reports on the status of elastic fibers in scar tissue. If appropriate stains are used, fine elastic fibers can be demonstrated in scars that have been present for more than 3 months.³¹ They increase progressively over time, but they are always thinner than in normal skin.

MARFAN'S SYNDROME

Marfan's syndrome (OMIM 154700) is a rare, autosomal dominant defect of connective tissue, with ocular, skeletal, and cardiovascular manifestations.⁶²² There is a wide range of overlapping phenotypes.⁶²³ Marfan's syndrome has a prevalence of 1 in 5000–10,000 individuals; up to 30% of cases represent new mutations. Cutaneous manifestations are of little clinical importance; they include striae distensae and elastosis perforans serpiginosa.⁶²⁴ Defects in the cross-linking and composition of collagen have been described, but abnormalities in elastic tissue (a mutation in the fibrillin-1 (*FBN1*) gene on chromosome 15q21.1) are the dominant feature.^{6,625} Defects in the fibrillin-2 gene (*FBN2*) cause a phenotypically related disorder.⁵ These various disorders have been called the microfibrilopathies.⁵

A study of 1013 probands with this syndrome and *FBN1* mutations attempted a genotype–phenotype correlation.⁶²³ Although no set of features was pathognomonic for a particular subtype of *FBN1* mutation, the occurrence of specific organ involvement differed significantly in some instances.⁶²³ Skin involvement (found in approximately half of the cases) correlated with PTC mutations (premature termination codons) in the *FBN1* gene.⁶²³

Histopathology

The striae distensae show the usual features of this lesion (see p. 368) with regeneration of elastic fibers.⁶²⁶ The lesions of elastosis perforans serpiginosa resemble those already described for this entity (see p. 385).

Clinically normal skin shows no detectable abnormality, although one study suggested that the elastic fibers looked slightly tortuous and fragmented.⁶²⁴ In some cases, thinning of the dermis, resulting from a diminished quantity of collagen due to thinner collagen bundles, has been noted.

Electron microscopy

Electron microscopy shows an increase in fine elastic fibers, possibly resulting from incomplete fusion of elastic fibers.⁶²⁴ Degenerative changes in elastic fibers have been observed in the lung.⁶²⁷

Cutaneous mucinoses

Introduction	406	Nephrogenic systemic fibrosis	410	Progressive mucinous histiocytosis	419
Dermal mucinoses	406	Reticular erythematous mucinosis (REM)	412	Secondary dermal mucinoses	419
Generalized myxedema	407	Scleredema	413	Follicular mucinoses	420
Pretibial myxedema (thyroid dermopathy)	407	Focal mucinosis	414	Follicular mucinosis (alopecia mucinosa)	420
Papular mucinosis and scleromyxedema	407	Digital mucous (myxoid) cyst	414	Secondary follicular mucinoses	421
Acral persistent papular mucinosis	410	Mucocele of the lip	416	Perifollicular mucinosis	421
Cutaneous mucinosis of infancy	410	Cutaneous myxoma and Carney's complex	417	Epithelial mucinoses	421
Self-healing juvenile cutaneous mucinosis	410	Nevus mucinosus (mucinous nevus)	418	Mucopolysaccharidoses	422

INTRODUCTION

The mucinoses are a diverse group of disorders that have in common the deposition of basophilic, finely granular and stringy material (mucin) in the connective tissues of the dermis (dermal mucinoses),^{1,2} in the pilosebaceous follicles (follicular mucinoses), or in the epidermis and tumors derived therefrom (epithelial mucinoses).³ The most important mucinoses are the dermal ones where glycosaminoglycans (GAGs), also known as acid mucopolysaccharides, accumulate in the dermis.^{4,5} GAGs are a major class of extracellular complex polysaccharides.⁶ There are four classes:

- Heparin/heparan
- Chondroitin/dermatan
- Keratan
- Hyaluronan (hyaluronic acid).

Hyaluronan (HA) and heparin sulfate comprise the major fraction of the vertebrate pericellular matrix.⁷ The total amount of HA in an adult is estimated to be 20 g, and turnover is approximately 15 g/day.⁷ It is found in the vitreous humor of the eye, the extracellular matrix, and the intercellular space of the epidermis, where it appears to be involved in cell–cell interactions. CD44 is thought to be the primary receptor for HA on cells.⁷

Hyaluronan, in contrast to the other GAGs, is nonsulfated and is synthesized not on the Golgi apparatus but, rather, on the inner face of the plasma membrane of the fibroblast.^{7,8} Three hyaluronan synthases (HAS) are involved in its synthesis. It is removed by lymphatics and degraded in the liver and lymph nodes. Polymer size confers specific functions on HA that include wound healing, angiogenesis, aspects of tumor growth, and host–pathogen interactions.⁷

Hyaluronan is highly hydrophilic, and water drawn into the matrix creates a turgor that enables it to withstand compressive forces.^{5,9} The loss of this water during paraffin processing results in residual basophilic strands and granules in widened dermal spaces in sections stained with

hematoxylin and eosin (H&E). Hyaluron is poorly fixed by 10% formalin, and some is also lost during tissue processing.

Fragmentation of the dermal collagen is quite common in the dermal mucinoses. Collagen type III is often reduced, although there is a compensatory increase in type I collagen.¹⁰

The pathogenetic mechanisms involved in the accumulation of mucin in the skin are poorly understood. In many of the mucinoses, there appears to be an increased production of acid mucopolysaccharides by fibroblasts, although in myxedema it has been suggested that impaired degradation leads to accumulation of mucin in the dermis (see later). Several of the cutaneous mucinoses have been reported in patients with HIV infection, although only the association with papular mucinosis (lichen myxedematosus) seems to be statistically significant.¹¹ The relationship between the infection and the mucin deposition is unclear.¹¹

In the mucopolysaccharidoses, which are best considered separately from the other mucinoses, the predominant dermal mucin is chondroitin sulfate, rather than hyaluronan.

The two most common methods used for demonstrating mucin in the skin are the Alcian blue technique at pH 2.5 and the colloidal iron stain, with which acid mucopolysaccharides are blue-green. Metachromasia of mucin is usually demonstrated with the toluidine blue or Giemsa methods. It has been suggested that fixation in a 1% solution of cetylpyridinium chloride in formalin, followed by colloidal iron staining of the paraffin sections, gives the best definition of glycosaminoglycans in the skin.¹²

The histological features of the various mucinoses are summarized in Table 13.1.

DERMAL MUCINOSES

The distribution of the glycosaminoglycans is said to differ in the various dermal mucinoses. However, in a comparative study some years ago, Matsuoka and colleagues found that the distribution of these

Table 13.1 Mucinoses – key histological features	
Disease	Histological features
Generalized myxedema	Subtle changes: mucin deposition often only perivascular or perifollicular; no fibroblast changes
Pretibial myxedema	Increased mucin often localized to mid and lower dermis; fibroblasts sometimes stellate, but not increased
Scleredema	Thickening of reticular dermis due to swelling and separation of collagen bundles; no significant hyperplasia of fibroblasts; variable interstitial mucin, sometimes minimal in late stages; no deep inflammatory infiltrate as in morphea
Scleromyxedema	Prominent fibroblastic proliferation and increased collagen; variable mucin increase
Papular mucinosis	Discrete form resembles focal mucinosis; slight proliferation of fibroblasts in generalized form
Acral persistent papular mucinosis	Resembles papular mucinosis but mucin deposition and fibroblast proliferation less pronounced
Cutaneous mucinosis of infancy	May be a variant of scleromyxedema
Nephrogenic systemic fibrosis	Resembles scleromyxedema but usually has subcutis involvement; less mucin; no plasma cells
Reticular erythematous mucinosis	Superficial and characteristic mid-dermal perivascular lymphocytic infiltrate; sometimes deeper extension around eccrine coils; mucin usually prominent
Focal mucinosis	Dome-shaped solitary nodule with prominent mucin in upper or entire dermis with variable collagen replacement
Digital mucous cyst	Mucinous pool with stellate fibroblasts resembling focal mucinosis, or a cavity with a myxoid connective tissue wall
Mucocele	Pseudocystic space with surrounding macrophages and vascular loose fibrous tissue or granulation tissue with mucin, muciphages, and inflammatory cells
Nevus mucinosus	Mucin in expanded papillary dermis; few fibroblasts present
Secondary dermal mucinoses	Mucin and changes of underlying disease such as lupus erythematosus, Degos' disease, Jessner's lymphocytic infiltrate, granuloma annulare, and dermatomyositis
Follicular mucinosis (alopecia mucinosa)	Mucin in hair follicles and attached sebaceous gland with some dissolution of cellular attachments; variable inflammatory infiltrate; infiltrate is dense and atypical in secondary follicular mucinosis complicating lymphoma or mycosis fungoides
Mucopolysaccharidoses	Metachromatic granules in fibroblasts and sometimes eccrine glands and keratinocytes; extracellular mucin in maculopapular lesions of Hunter's syndrome

substances is generally not diagnostically specific.¹² Accordingly, clinicopathological correlation is important in this group. Sclerodema and scleromyxedema differ from the other dermal mucinoses by the presence of collagen deposition and fibroblast hypertrophy and/or hyperplasia, in addition to the deposition of mucin.

Alajlan and Ackerman have questioned the legitimacy of the concept of the dermal mucinoses.¹³ They claim that the term has not yet been defined meaningfully and that each of the 'so-called dermal mucinoses can be identified on the basis of distinctive clinical and histopathological features'.¹³

The case of cutis verticis gyrata caused by the deposition of mucin in the dermis was not associated with any of the mucinoses described elsewhere, so it is mentioned here for completeness.¹⁴

GENERALIZED MYXEDEMA

Myxedema is one of several cutaneous changes in hypothyroidism.^{4,15-17} The changes are most pronounced around the eyes, nose, and cheeks, often giving a characteristic facies, and also on the distal extremities. The skin is cold, dry, and pale with widespread xerosis, especially on the extensor surfaces.¹⁸ A diffuse, nonscarring alopecia may be present.¹⁹ Cutis verticis gyrata is a rare presentation.²⁰

Palmoplantar keratoderma is a poorly recognized presentation of myxedema.²¹ Glycosaminoglycans are deposited in other organs of the body as well as the skin, and it has been suggested that there is impaired degradation, rather than increased synthesis, of these substances.^{5,22} Muscle weakness is sometimes present.²³

Generalized and pretibial myxedema have been grouped together as 'dysthyroidotic mucinoses' in the excellent review of the cutaneous mucinoses by Rongioletti and Rebora.²⁴

Histopathology

In most cases, the changes are subtle, with only small amounts of mucin in the dermis.⁵ This is predominantly hyaluronic acid. Sometimes this material is deposited only focally around vessels and hair follicles.⁵ There may be mild hyperkeratosis and keratotic follicular plugging, reflecting the xerosis that is present clinically. Elastic fibers are sometimes fragmented and reduced in amount.

PRETIBIAL MYXEDEMA (THYROID DERMOPATHY)

Pretibial myxedema (thyroid dermopathy) is found in 1–4% of patients with Graves' disease, particularly those with exophthalmos, but it may not develop until after the correction of the hyperthyroidism.²⁵ Rarely, it may precede the diagnosis of hyperthyroidism.²⁶ It may also occur in patients with non-thyrotoxic Graves' disease²⁷ and occasionally in association with Hashimoto's thyroiditis.²⁸ It has been associated with an ectopic, hyperplastic nodule arising in a thyroglossal duct residue.²⁹ Pretibial myxedema has been reported in euthyroid patients with stasis dermatitis³⁰ and in patients with morbid obesity who have lower leg lymphedema.³¹

It presents as sharply circumscribed nodular lesions, diffuse nonpitting edema, or elephantiasis-like thickening of the skin.^{18,32-34} There may be overlap of these lesions or progression from nodular to more diffuse plaques.²⁵ The anterior aspect of the lower legs, sometimes with spread to the dorsum of the feet, is the most usual site of involvement, although, rarely, the upper trunk, upper extremities, and even the face, neck, or ears have been involved.³⁵⁻³⁸ Preradial myxedema has been described and may accompany pretibial myxedema. It may be frequently overlooked. An example in a euthyroid patient has been reported.³⁹ Edema of the eyelids, not associated with the deposition of mucin, may occur in hyperthyroidism.⁴⁰ Localization to scar tissue, skin grafts, and the toes has been reported,⁴¹⁻⁴⁶ and an association between localized myxedema and trauma, surgical or otherwise, has

been noted on a number of occasions.^{47,48} Acropachy (digital clubbing and diaphysal proliferation) is rare, with an incidence of less than 1%.⁴⁹ Because sites other than the pretibial region can be affected, the term thyroid dermopathy is more appropriate.¹⁸ Early detection of pretibial myxedema can be accomplished with the use of digital infrared thermal imaging and high-resolution ultrasonography.⁵⁰ Slow resolution of the lesions often occurs after many years. Hyperhidrosis and/or hypertrichosis, limited to areas of thyroid dermopathy, have been reported.^{18,51}

The precise pathogenesis of pretibial myxedema is unknown. The theory that pretibial myxedema results from the stimulation of fibroblasts by LATS (long-acting thyroid stimulator) is no longer tenable, although one or multiple other substances or autoantibodies are presumably involved.^{35,52} A circulating factor that stimulates increased synthesis of glycosaminoglycans by normal skin fibroblasts is present in increased amounts in patients with pretibial myxedema.^{53,54} Furthermore, fibroblasts from pretibial skin cultured in the presence of serum from patients with pretibial myxedema produce increased amounts of hyaluronic acid.⁵⁵ The response of refractory cases of pretibial myxedema to octreotide (a somatostatin analogue with insulin-like growth factor-1 (IGF-1) antagonist properties) suggests that expression of IGF-1 receptor on fibroblasts may be upregulated in this condition, leading to increased secretion of hyaluronic acid.⁵⁶ Other explanations for this effect are possible. There is no primary lymphatic abnormality.²⁵ Hydrostatic forces appear to play a role in the localization of the pretibial mucinosis.⁵⁷ Topical corticosteroids under occlusion have been effective when used within several months of the appearance of the lesions.⁵⁸ Multipoint subcutaneous injections of long-acting corticosteroids have also been worthwhile.⁵⁹

Histopathology

There are large amounts of mucin deposited in the dermis, particularly in the mid and lower thirds (Figs. 13.1 and 13.2). Initial deposition is often in the papillary dermis, with subsequent extension into the deeper tissues.¹⁸ This manifests as basophilic threads and granular material with wide separation of collagen bundles.⁴ There is no increase in fibroblasts, although a few stellate forms may be present. There may be overlying hyperkeratosis, which can be quite marked in clinically verrucous lesions.⁶⁰ A mild superficial perivascular chronic inflammatory cell infiltrate is often present.²² In patients with underlying stasis dermatitis, the deposition of mucin is within the papillary dermis with sparing of the reticular dermis.³⁰ Angioplasmia and hemosiderin deposition are additional features in the dermis.

Elastic tissue stains show fragmentation and a reduction in elastic tissue, a finding confirmed on electron microscopy,⁶¹ which also shows microfibrils with knobs (glycosaminoglycans)⁶² or amorphous material (glycoproteins)⁶³ on the surface of fibroblasts that have dilated endoplasmic reticulum.^{62,63}

PAPULAR MUCINOSIS AND SCLEROMYXEDEMA

Papular mucinosis (lichen myxedematosus) is a rare cutaneous mucinosis in which multiple, asymptomatic, pale or waxy papules, 2–3 mm in diameter, develop on the hands, forearms, face, neck, and upper trunk.⁶⁴ A discrete papular variant also occurs.⁶⁵ It has been reported, rarely, in patients with hepatitis C⁶⁶ and with HIV infection^{11,67-71} and also in the L-tryptophan-induced eosinophilia-myalgia syndrome,⁷² in generalized morphea,⁷³ in subclinical hypothyroidism,^{74,75} and in patients with morbid obesity.⁷⁶ Self-healing cases have been reported,⁷⁷ indicating the overlap between this entity and self-healing cutaneous mucinosis (see later). In a case of papular mucinosis associated with HIV disease, resolution of the lesions gradually occurred on HAART therapy, accompanied by an increase in CD4 counts and a reduction in the HIV viral load.⁷⁸ Papular mucinosis with systemic involvement has also been reported.⁷⁹

Figure 13.1 Pretibial myxedema. (A) There is pallor of the dermis and (B) the collagen bundles in the dermis are widely spaced, a consequence of the increased amount of interstitial mucin. (H&E)

*Scleromyxedema*⁸⁰ is a variant in which lichenoid papules and plaques are accompanied by skin thickening involving almost the entire body.^{81–84} The face, neck, hands, and forearms are sites of predilection. Involvement of the glabella region may give rise to bovine or leonine facies.^{81,85} The Koebner phenomenon due to a scratch test has been reported.⁸⁶ Adults in the third to fifth decades or older are most commonly affected. A paraproteinemia, particularly of IgG λ type, is almost invariably present in scleromyxedema and sometimes in papular mucinosis.^{4,87,88} Other classes of immunoglobulins are sometimes present,⁸⁹ a few patients have a normal immunoglobulin profile.⁹⁰

Figure 13.2 Pretibial myxedema. There are large amounts of dermal mucin. (Alcian blue)

Multiple myeloma and Waldenström's macroglobulinemia are rare associations.^{91,92} Bizarre neurological symptoms are also reported.⁹³ A variant form of scleromyxedema termed the 'dermato-neuro syndrome' consists of a flu-like prodrome, followed by fever, convulsions, and coma.⁹⁴ Underlying carcinoma,^{64,95,96} including thymic carcinoma,⁹⁷ chronic hepatitis C,⁹⁸ pachydermoperiostosis,⁶⁴ dermatomyositis,⁹⁹ scleroderma,^{92,100} atherosclerosis,¹⁰¹ esophageal aperistalsis,¹⁰² multiple keratoacanthomas,⁸⁹ and cardiomyopathy¹⁰³ have all been reported in association with scleromyxedema.⁹²

Scleromyxedema is usually progressive, but spontaneous resolution has been reported.¹⁰⁴ Mucin has been noted in other organs in a few autopsy cases, but it has been specifically excluded in others.^{64,105–107} Rarely, hypothyroidism has been present.^{108,109}

In 2001, Rongioletti and Rebora provided an updated classification of papular mucinosis/lichen myxedematosus/scleromyxedema.¹¹⁰ The generalized and sclerodermoid form is best known as scleromyxedema. The localized form has several subtypes.¹¹¹ They include acral persistent papular mucinosis, self-healing papular mucinosis (juvenile and adult variants), papular mucinosis of infancy, and nodular lichen myxedematosus as variants, despite the absence of fibrosis in some of these conditions. Atypical or intermediate forms have also been described. Recent examples include localized papular mucinosis associated with IgA nephropathy,¹¹² and both scleromyxedema¹¹³ and papular mucinosis^{114,115} with an interstitial granulomatous configuration on biopsy.

It has been postulated that a serum factor stimulates fibroblast proliferation and increased production of glycosaminoglycans.^{100,116} Whether this factor is identical to the monoclonal immunoglobulin is controversial.^{92,117} In one study, cultured skin fibroblasts from a patient with scleromyxedema produced an IgG immunoglobulin.¹¹⁸

An unusual scleromyxedema-like disease has been reported in renal dialysis patients and in other circumstances. The terms 'nephrogenic fibrosing dermopathy' and 'nephrogenic systemic fibrosis' have been applied to this condition. It is considered, in detail, later.

Response to high- and low-dose intravenous immunoglobulin, interferon- α , prednisone, retinoids, high-dose pulsed methylprednisolone, thalidomide, melphalan, electron-beam therapy, extracorporeal photopheresis, and autologous stem cell transplantation has been reported.^{119–135} Response to intravenous immunoglobulin is not permanent, and maintenance infusions are generally required.⁸⁰ The proteasome inhibitor bortezomib, used in the management of relapsed multiple myeloma and mantle cell lymphoma, has also been successfully employed in treating scleromyxedema.^{136,137} The localized type has been treated with tacrolimus ointment.¹¹¹

Figure 13.3 Scleromyxedema. The dermis contains an increase in fibroblasts, collagen, and interstitial mucin. (H&E)

Figure 13.4 Scleromyxedema. The characteristic triad of an increase in fibroblasts, collagen, and mucin is present. (H&E)

Histopathology

The histopathological features of *scleromyxedema* are the most precise of any of the mucinoses.^{22,81} In addition to the dermal deposits of mucin, there is a marked proliferation of fibroblasts and increased collagen deposition in the upper and mid dermis (**Figs. 13.3 and 13.4**).²² The fibroblasts are irregularly arranged, and the collagen, which is most pronounced in older lesions, has a whorled pattern. Flattening of the epidermis and atrophy of pilosebaceous follicles are secondary changes. Sweat duct proliferation is rare.¹³⁸ Elastic fibers are often fragmented.¹¹⁸ A sparse perivascular infiltrate of lymphocytes is often present. Occasionally, eosinophils^{102,105} or mast cells¹³⁹ are prominent. In one case, there was a prominent perivascular infiltrate of plasma cells that were monotypic for γ light chain.¹⁴⁰

As noted previously, an unusual granulomatous variant of scleromyxedema has been reported, and similar findings have been reported in localized papular mucinosis.^{114,115} The microscopic findings closely resembled interstitial granuloma annulare.¹⁴¹ In one case, initial findings resembled xanthogranuloma, complete with Touton giant cells.¹¹⁴ Initial biopsies may show a predominantly interstitial granulomatous configuration, whereas subsequent specimens show

changes more consistent with scleromyxedema¹¹⁴ or diffuse dermal mucin deposition.¹¹⁵ Changes of scleromyxedema have also been found in an enlarged mediastinal lymph node from a patient with the disease.¹⁴²

Electron microscopy

Ultrastructurally, the fibroblasts have prominent rough endoplasmic reticulum. Proteoglycans are present between the collagen bundles.¹⁴³

The changes in *papular mucinosis* are not as characteristic. In the discrete form, the changes may be indistinguishable from focal mucinosis,¹⁴⁴ although in the more generalized cases a slight proliferation of fibroblasts is often present in addition to the mucin deposition in the upper dermis (**Fig. 13.5**).¹⁰⁸ Sclerotic features are absent.⁷⁶

Differential diagnosis

Most other forms of mucinosis show either local aggregates of dense mucin or mucin interstitially distributed between collagen bundles, in the absence of significant fibroblast proliferation and increased collagen deposition. Young dermal scars can show features that are similar to those of scleromyxedema, but a history of prior therapy or trauma

Figure 13.5 Papular mucinosis. This example, from a patient with generalized disease, shows proliferation of fibroblasts in addition to mucin deposition in the upper dermis. (H&E)

can usually be elicited, and sharp demarcation is characteristic of most surgical scars. A major differential diagnostic consideration is nephrogenic systemic fibrosis (formerly nephrogenic fibrosing dermopathy) (see later discussion). Microscopically, the changes are quite similar to those of scleromyxedema, and distinction depends in part on clinicopathologic correlation. However, there are two important histopathologic differences: (1) the increased expression of procollagen I in scleromyxedema¹⁴⁵ and (2) the greater depth of involvement in nephrogenic systemic fibrosis, in which changes extend into the deep dermis and subcutis.¹⁴⁶

ACRAL PERSISTENT PAPULAR MUCINOSIS

Acral persistent papular mucinosis, which affects mainly women, is characterized by discrete, flesh-colored papules 2–5 mm in diameter on the back of the hands and, less commonly, on the forearms^{147–154} and calves.¹⁵⁵ Approximately 30 cases have been reported.¹⁵⁶ The lesions increase in number with the years. There is usually no associated disease.¹⁵⁷ It is best regarded as a variant of papular mucinosis (lichen myxedematosus).^{110,158}

A patient with a self-healing plaque on the dorsum of one hand has been reported as **self-healing localized cutaneous mucinosis**.¹⁵⁹ This case does not fit neatly into any of the current classifications of the mucinoses.

The lesions in acral persistent papular mucinosis are asymptomatic. In one example, electrocoagulation was successfully used to remove the lesions, with excellent cosmetic results.¹⁶⁰

Histopathology

This condition shares some histological features with papular mucinosis (discussed previously) by having mucin deposition and a proliferation of fibroblasts. However, the mucin is usually confined to the upper and mid dermis, in contrast to the more widespread distribution in the dermis in papular mucinosis. A spared grenz zone is usually present.¹⁵⁸ Furthermore, fibroblastic proliferation is not as pronounced as in papular mucinosis; it may be absent in early cases.¹⁵⁴

Electron microscopy

Altered fibroblasts with concentric lysosomal structures in their cytoplasm have been reported.¹⁵⁰

CUTANEOUS MUCINOSIS OF INFANCY

There have been several reports of infants presenting with multiple, small, papular lesions on the upper extremities or trunk.^{2,161–164} The distribution of the lesions and their early onset raise the possibility that the lesions reported are connective tissue nevi of proteoglycan type (nevus mucinosus).^{165,166} There has been abundant mucin in the papillary dermis, no significant increase in fibroblasts, and a few chronic inflammatory cells in a perivascular distribution. In one case, however, there was both fibrosis and fibroblast proliferation, leading the authors to suggest that cutaneous mucinosis of infancy could be a pediatric form of papular mucinosis (lichen myxedematosus).¹⁶⁷ This is the currently accepted view.

SELF-HEALING JUVENILE CUTANEOUS MUCINOSIS

There have been several reports of a cutaneous mucinosis characterized by the rapid onset in childhood of infiltrated plaques on the head and torso and deep nodules on the face and periarticular region, with spontaneous resolution in weeks or months.^{168–173} Other reports have described a familial variant¹⁷⁴ and rare cases in adults.^{175,176} The existence of self-healing cases of papular mucinosis (lichen myxedematosus)⁷⁷ illustrates the arbitrary nature of the current classification of some mucinoses and lends support to the notion of Rongioletti and Rebora in 2001 that many of these entities are clinical variants of papular mucinosis (lichen myxedematosus).^{110,177} Notwithstanding this view, this mucinosis is thought to represent a reactive or reparative response to some antigenic stimulation, such as inflammation or a viral infection.¹⁷⁸ It has developed in a child with a nephroblastoma who was undergoing chemotherapy.¹⁷²

Histopathology

Biopsies of this condition have shown a normal epidermis overlying an ‘edematous’ dermis resulting from mucin separating collagen bundles in the dermis. An increase in fibroblasts has been reported.¹⁷² A sparse perivascular inflammatory cell infiltrate is sometimes present, and CD68⁺ macrophages are present in the base of the mucin deposits.¹⁷⁹

The subcutaneous nodules are composed of large mucinous lobules (islands) separated by fibrous tissue bands containing a sparse population of fibroblast-like spindled cells.¹⁷⁸ A sparse lymphocytic infiltrate may be present. The mucinous lobules, which stain strongly for Alcian blue at pH 2.5, contain a lobular array of stellate, spindled, and, in some cases, rhabdoid or gangliocyte-like giant cells.^{178–181} There is some resemblance to proliferative fasciitis.¹⁸⁰ The dermis overlying these subcutaneous nodules usually shows a mild increase in mucin but no increase in fibroblasts. Stains for CD34, smooth muscle actin, muscle-specific actin, cytokeratins, and epithelial membrane antigen are negative.¹⁷⁸

Differential diagnosis

It has been noted that nodular lesions of self-healing juvenile cutaneous mucinosis may show minimal or no dermal mucin deposition, and the subcutaneous changes can overlap with those of proliferative fasciitis and nonspecific panniculitis. Therefore, clinicopathologic correlation is essential in these cases.¹⁸²

NEPHROGENIC SYSTEMIC FIBROSIS

This condition, previously called nephrogenic fibrosing dermopathy, is a scleromyxedema-like disease of the skin and other organs, including esophagus, lungs, heart, skeletal muscle, and kidneys – hence the

preferred term nephrogenic systemic fibrosis.¹⁸³ It occurs in a subset of patients with renal insufficiency.^{184–187} Renal dialysis is not a prerequisite for its development.¹⁸⁸ It may follow severe acute kidney injury.¹⁸⁹ Cowper has done much of the work in describing the features of this entity.^{186,190–192}

It evolves over a period of days to weeks with thickening and hardening of the skin, muscle weakness, and generalized pain. Diaphragmatic involvement is a serious complication that can lead to death.^{193–195} The skin lesions are indurated papules and plaques, involving predominantly the trunk and extremities.^{196,197} Facial papules are rare.¹⁹⁸ A patient with lesions limited to the breast, mimicking inflammatory breast carcinoma, has been reported.¹⁹⁹ In another case, there was a localized plaque on the forearm along a vein that was traumatized during the infusion of erythropoietin.²⁰⁰ This substance has been suggested as a possible cofactor in producing this disease.²⁰¹ In a small series of patients with nephrogenic systemic fibrosis (NSF), one patient apparently had no known exposure to gadolinium (and mass spectroscopy testing failed to reveal gadolinium) but had resolution of symptoms when darbepoietin administration was changed from subcutaneous to intravenous injection (see later).²⁰² Pediatric cases are rare.²⁰³

The sudden appearance of this condition in 1997 and its association with renal insufficiency led to an extensive search for the etiological agent. In 2006, gadolinium-based contrast agents used in magnetic resonance imaging (MRI) were implicated as the causative agent in patients who had renal disease and were often acidotic.²⁰⁴ Gadolinium had been used a few weeks prior to the onset of the disease in each case.^{205–210} Gadolinium has since been identified in the tissues of affected patients.^{186,211–214} It has been suggested that the gadolinium product involved is gadodiamide (a nonionic linear chelate).²¹⁵ Several recent studies using Synchrotron X-ray fluorescence microscopy have clarified the nature of the gadolinium deposits in tissues. Gradients of gadolinium deposition in tissue have been shown to correspond to fibrosis and cellularity, and adnexal deposition correlates with high calcium and zinc content.²¹⁶ Furthermore, gadolinium in tissue is coordinated mainly by phosphate in a sodium–calcium–phosphate material and not by the gadolinium-based contrast agent.²¹⁷ The fibrosis caused by this agent may result from the upregulation of transglutaminases in the affected tissue.²¹⁸ Transforming growth factor- β also plays a role in producing the fibrosis.²¹⁹ It is known that phosphoinositol 3-kinase (PI3K) and mammalian target of rapamycin (mTOR) pathways are important mediators of cell cycle progression and proliferation (mTOR belongs to the PI3K-related kinase protein family). In fact, erythropoietin (a possible cofactor in this disease) is known to activate these pathways, and discontinuation of erythropoietin has led to improvement in some patients with NSF.²²⁰ In one case, proliferating fibrocytes were shown to express phospho-70 S6 kinase, a protein downstream of PI3K, and treatment with rapamycin resulted in significant clinical improvement.²²⁰ There may also be a contributing role for β -blockers in patients developing NSF who have received gadolinium contrast agents.²⁰²

Parenthetically, the author (D.W.) has never seen a case, possibly because the dose of gadolinium used in Brisbane is lower than in the United States. NSF has recently been reported in a gadolinium-naïve renal transplant recipient.²²¹ A recent study of a large group (2053) of nondialysis patients with chronic renal disease receiving gadolinium-enhanced MRI showed that none of them developed NSF over a mean follow-up period of more than 28 months. A variety of forms of gadolinium were used in the study, including gadodiamide. The authors concluded that the risk for this disease is minimal in patients with stable stage 3 or 4 chronic renal disease (estimated glomerular filtration rate of more than 15 ml/min) with appropriate precautions; among these are use of the minimal necessary dosage of gadolinium and the use of safer, more stable gadolinium compounds (those with cyclic, ionic structures) in higher risk patients.²²²

Improvement in cutaneous lesions has been reported with UVA1 phototherapy,²²³ high-dose intravenous immunoglobulin,²²⁴ and extracorporeal photopheresis.^{215,225} Retinoids have been used with PUVA therapy, giving significant clinical improvement.²²⁶ The disease has been improved or stabilized with the fusion protein alefacept.²²⁷

It is hoped that this disease is destined to become another historical footnote, like the eosinophilia–myalgia syndrome and others.²²⁸

Histopathology

The dermis and septa of the subcutaneous fat are thickened by dense collagen bundles in haphazard array. There is a proliferation of plump spindle-shaped cells and variable interstitial mucin (**Fig. 13.6a**).^{229–233} Histiocytes positive for CD68 and dendrocytes that are positive for factor XIIIa are also present.²³⁴ Many of the spindle-shaped cells show dual immunoreactivity for CD34 and procollagen.^{235–237} CD34⁺ spindle cells form a reticular or parallel arrangement that can be quite complex (**Fig. 13.7**); the dendritic processes of these cells form what

Figure 13.6 Nephrogenic systemic fibrosis. (A) There is a 'busy' dermis with thickened, haphazard collagen, interstitial mucin, and numerous plump spindle-shaped cells. (B) Subcutaneous involvement is extensive and provides a differentiating feature from scleromyxedema. (H&E)

Figure 13.7 Nephrogenic systemic fibrosis. There is a reticular to parallel arrangement of CD34⁺ spindled cells. (Immunohistochemical staining for CD34)

has been called a 'tram-track' configuration around central elastic fibers.²³⁸ Prussian blue staining has shown that there are iron deposits within fibrocytes in a number of cases of NSF, correlating with the use of gadolinium-based contrast agents.²³⁹ Small multinucleate histiocytes have also been described.²³⁰ Various elastic tissue changes have been reported, including the presence of elongated fibers,²³³ calcification of elastic fibers resembling pseudoxanthoma elasticum,²⁴⁰ and the rare development of generalized elastolysis.²⁴¹ Calciophylaxis, metastatic calcification,^{242,243} and osseous metaplasia uncommonly develop.²⁴⁴ Osseous sclerotic bodies with entrapment of elastic fibers are sometimes observed and, when present, are strongly suggestive of the diagnosis.²⁴⁵ These are considered variations of the so-called 'lollipop lesion' – sclerotic, amorphous eosinophilic bodies that appear to be pierced by elastic fibers.²⁴⁶ Osteoclast-like giant cells and subcutaneous fat necrosis have also been reported,^{242,247} as has a septal panniculitis mimicking erythema nodosum.²⁴⁸ Hyaluronan, a mucin that is poorly retained in formalin-fixed material, can be demonstrated in the papillary dermis by special techniques,²⁴⁹ and cultured fibroblasts from lesional skin also produce increased amounts of this mucin.²⁵⁰

A clinicopathologic classification system has been devised for NSF. Clinical findings include major criteria (patterned plaques, joint contractures, 'cobblestoning', and marked induration or peau d'orange appearance) and minor criteria (puckering or linear banding, superficial plaque or patch, dermal papules, and scleral plaques in those younger than the age of 45 years). Histopathologic findings include increased dermal cellularity, CD34⁺ cells with tram-tracking, thick and thin collagen bundles, preserved elastic fibers, septal subcutaneous involvement, and osseous metaplasia. Each of the microscopic changes receives a score of +1 except that the absence of elastic fibers receives a score of -1 and osseous metaplasia receives a score of +3. The combination of clinical and histopathologic scores allows establishment of an accurate diagnosis.²³⁸

Differential diagnosis

The distinction of NSF from scleromyxedema was discussed previously under the latter disorder. Although one study failed to find any histological differences from scleromyxedema,²⁵¹ the presence of subcutaneous involvement in nephrogenic systemic fibrosis is a distinguishing feature.¹⁴⁶ Mucin deposition is less,²⁵² but this may, in part, be related to an increased proportion of poorly retained hyaluronan. Plasma cells are usually not present in this condition, but small clusters may be present in scleromyxedema.²⁵² Other sclerosing conditions,

such as morphea, scleroderma, or stiff skin syndrome, demonstrate less cellularity, particularly in more mature lesions. Morphea tends to show lympho-plasmacellular infiltrates around vessels and at the dermal-subcutaneous interface, especially in earlier lesions. In addition to being relatively acellular, scleroderma demonstrates widening of spaces between sclerotic collagen bundles with mucin deposition in these spaces. Pseudoxanthoma elasticum shows rather unique changes in elastic fibers that ordinarily would not be confused with NSF, although secondary PXE-like changes can sometimes be seen within the deep dermis or subcutis in a variety of sclerosing conditions. In calciophylaxis, the dermis overlying subcutaneous vascular changes may take on an amorphous, smudged appearance due to ischemia; this may be accompanied by epidermal or sweat gland necrosis. In addition, calciophylaxis and NSF can coexist. Finding iron deposits in fibrocytes can also be helpful in making the diagnosis because these deposits have not been seen in scleromyxedema, morphea, or scleroderma.²³⁹ Sclerotic bodies may be more indicative of gadolinium exposure than NSF per se, as indicated by Bhawan *et al.*, who described a patient with chronic renal failure who received gadolinium but did not have NSF and was found to have sclerotic bodies in most of his excision specimens for squamous cell carcinomas.²⁵³

RETICULAR ERYTHEMATOUS MUCINOSIS (REM)

Reticular erythematous mucinosis (REM) was first described by Steigleder and colleagues in 1974.²⁵⁴ It presents with erythematous maculopapules and infiltrated plaques, often with a reticulated or net-like pattern, in the midline of the back or chest, sometimes spreading to the upper abdomen.^{255–259} Rarely, the face and arms²⁶⁰ are involved, and one case is said to have involved the gums.²⁶¹ There is a predilection for young to middle-aged females. Sunlight and hormonal influences may cause exacerbations and induce mild pruritus.^{4,259,262} The lesions may subside after many years. Progression to cutaneous lupus erythematosus sometimes occurs, which is one of the reasons why Ackerman regards this condition as a variant of lupus erythematosus. Two cases of mycosis fungoides that clinically mimicked REM have been reported.²⁶³ Associations with other malignancies (breast carcinoma, colon carcinoma, and Hodgkin's disease) and with autoimmune disorders (Hashimoto's thyroiditis, diabetes mellitus, and ulcerative colitis) have also been reported.²⁶⁴

One study showed that fibroblasts from lesional skin exhibit an abnormal response to exogenous interleukin-1 β ,²⁶⁵ but a more recent study showed that the accumulation of hyaluronan in REM may be related to populations of factor XIIIa⁺/HAS2⁺ dermal dendrocytes rather than to dermal fibroblasts.²⁶⁶ HAS2 is one of three genetically distinct isoforms of HAS, the enzyme thought to be responsible for the synthesis of hyaluronan, a major component of the dermal matrix.²⁶⁶

Topical tacrolimus and UVA1 radiation have been found to be a safe alternative to systemic antimalarials in the treatment of this condition.^{267,268}

Histopathology

There is a mild superficial and mid-dermal perivascular infiltrate with variable deep perivascular extension, the latter sometimes being restricted to the region of the eccrine glands (Fig. 13.8).²⁵⁵ There may be some perifollicular infiltrate as well. This infiltrate is predominantly lymphocytic (helper T cells),²⁶⁹ with a few admixed mast cells, histiocytes, and factor XIIIa-positive dendrocytes.²⁶⁸ There is slight vascular dilatation and, sometimes, focal mild hemorrhage in the upper dermis.²⁶⁰

There is separation of dermal collagen bundles, and variable amounts of stringy basophilic mucin can be seen predominantly in the upper and mid dermis (Fig. 13.9). The mucin is most conspicuous around the infiltrate and appendages and within the upper dermis.²⁵⁹ A few stellate

Figure 13.8 Reticular erythematous mucinosis. (A) There is a superficial and deep infiltrate of lymphocytes and an increase in interstitial mucin. (B) This further example shows overlap features with tumid lupus erythematosus, although clinically the patient initially presented with reticular erythematous mucinosis. (H&E)

Figure 13.9 Reticular erythematous mucinosis. There is increased mucin throughout the dermis. (Alcian blue)

cells may be present. The epidermis is usually normal, although mild exocytosis with spongiosis and focal lichenoid inflammation have been reported.²⁵⁹

The mucin gives variable staining reactions. Colloidal iron staining is superior to Alcian blue, which occasionally has failed to demonstrate mucin.^{270,271} The material is not usually metachromatic with toluidine blue.²⁷¹ Staining with colloidal iron and Alcian blue will be negative following digestion with hyaluronidase. There may be focal fragmentation of elastic fibers.²⁷⁰ The mucin is largely hyaluronan, which is not well fixed by formalin.²⁶⁸

Direct immunofluorescence has shown the deposition of immunoglobulins, particularly IgM, and some C3, along the basal layer in several cases,^{272–274} lending support for the view that REM is a subset of lupus erythematosus.

Electron microscopy

Electron microscopy shows widening of the intercollagenous spaces, focal fragmentation of elastic fibers, and some active fibroblasts.²⁷⁵ Numerous tubular aggregates have also been seen in endothelial cells, pericytes, and some dermal macrophages.^{270,276}

Differential diagnosis

The combination of uninvolved epidermis, perivascular and perifollicular lymphocytic infiltrates, and dermal mucin deposition is also seen in tumid lupus erythematosus and lymphocytic infiltration of Jessner. Microscopic and even clinical distinction among these conditions may not always be possible. This has led to the speculation that these entities may be either closely related or actual manifestations of the same disease.

SCLEREDEMA

Scleredema (scleredema adultorum of Buschke) is characterized by the development of nonpitting induration of the skin with a predilection for symmetrical involvement of the posterior neck, the shoulders, the upper trunk, and the face.^{277,278} Localization to the thighs and periorbital region has been reported.^{279,280} In cases of more widespread involvement, the upper part of the body is always involved much more than the lower part, and the feet are spared. The condition occurs at all ages, although nearly 50% of cases develop in children and adolescents.²⁸¹ There is a predilection for females.

There are several different clinical settings.^{282,283} In one group, the onset is sudden and follows days to weeks after an acute febrile illness caused by streptococci, mycoplasma,²⁸⁴ or viruses. A case occurring in association with HIV infection has been reported.¹¹ It has followed scabies infestation complicated by secondary bacterial infection with streptococci.²⁸⁵ Spontaneous resolution occurs in approximately one-third of the post-infectious group after 6–18 months. This group is now seen less frequently than in the past. Another clinical group has an insidious onset, without any predisposing illness, and a protracted course. The third group is associated with insulin-dependent, maturity-onset diabetes, which is difficult to control.^{286–289} Vascular complications of diabetes are common.²⁹⁰ It can also be associated with type 2 diabetes.^{291,292} A fourth group is associated with a monoclonal gammopathy.^{293–303} Extracorporeal photopheresis and chemotherapy have been used to treat such cases.^{304,305} Other associations are mechanical stress,³⁰⁶ carcinoma of the gallbladder,³⁰⁷ adrenocortical adenoma, a pituitary ACTH-producing microadenoma,³⁰⁸ and rheumatoid arthritis.³⁰⁹ Scleredema is insidious in onset and prolonged in its course.

Systemic manifestations such as ECG changes, serosal effusions, and involvement of skeletal, ocular, and tongue musculature may develop. Cutaneous abscesses or cellulitis may precede or follow the onset of the condition.^{310,311} Rarely, there is erythema at sites of skin thickening.³¹² Two cases with overlap features between scleredema and stiff skin syndrome have been reported.³¹³

Scleredema is characterized by the accumulation of glycosaminoglycans, particularly hyaluronan, in the dermis with concurrent dermal sclerosis. The etiology is unknown, although fibroblasts from the fibrotic skin of patients with scleredema show enhanced collagen production and elevated type I procollagen messenger RNA levels in the cultured fibroblasts.²⁹⁵ This suggests that fibroblasts from involved skin have a biosynthetically activated phenotype.³¹⁴

Scleredema has been successfully treated with UVA1 phototherapy.³¹⁵ Post-streptococcal scleredema has been treated with intravenous immunoglobulins.³¹⁶

Histopathology^{277,293}

The epidermis is usually unaffected except for some effacement of the rete ridge pattern and occasionally mild basal hyperpigmentation.³¹⁷ Hyperkeratosis is rare.³¹⁸ There is thickening of the reticular dermis, with collagen extending also into the subcutis. The collagen fibers are swollen and separated from one another. The extent of this separation, which mirrors the amount of interstitial mucopolysaccharide present, depends on the stage of the disease (**Fig. 13.10**). This material may only be present in noticeable amounts at the onset of the disease.²⁸³ Multiple biopsies and the use of several stains may be necessary to demonstrate the dermal mucin.³¹⁹ Sometimes it is most prominent in the lower dermis.³²⁰ Cetylpyridinium has been proposed as a superior fixative to formalin for the preservation of the interstitial mucopolysaccharides.²⁸¹ These may subsequently be stained with Alcian blue or toluidine blue (pH 5.0 or 7.0) or with colloidal iron. Cryostat sections of unfixed material usually result in the optimal preservation of the interstitial hyaluronan.

Other features of scleredema include preservation of the appendages and an increase in mast cells.³²¹ Other inflammatory cells are sparse. Elastic fibers are reduced and may be fragmented.³¹⁷

The acellular fibrosis of the dermis in scleredema contrasts with the marked fibroblastic proliferation seen in scleromyxedema and the patchy deep inflammatory cell infiltrate seen at the advancing edge of plaques of morphea.

Electron microscopy

Electron microscopy shows thickened collagen fibers with widening of the interfibrillar spaces.²⁹³ The fibroblasts have prominent rough endoplasmic reticulum.²⁹³

Differential diagnosis

Marked dermal thickening, exaggerated fenestration of collagen bundles, and interstitial mucin deposition are unique features that usually enable distinction from other forms of cutaneous mucin deposition, such as focal mucinosis. The fibrosis and admixture of fibroblasts seen in nephrogenic systemic fibrosis, scleromyxedema, and some forms of papular mucinosis are not observed, and the absence of inflammatory changes argues against conditions such as granuloma annulare or reticular erythematous mucinosis. The resemblance to scleroderma (or morphea) is largely in name only; those conditions feature thickened but compact dermal collagen, and fenestration of collagen bundles or mucin deposition are not apparent. Appendageal atrophy is a feature of scleroderma and morphea but not scleredema, and often those disorders show lymphoplasmacytic inflammation at the dermal–subcutaneous interface, septal panniculitis, and/or lipoatrophy (particularly in morphea). Another potentially confusing condition, again in name only, is sclerema neonatorum. That disease is confined to newborns; characterized by cold, rigid, board-like skin; and microscopically shows needle-shaped clefts within the subcutis, representing lipids that have dissolved during tissue processing.

FOCAL MUCINOSIS

Focal mucinosis usually presents as a solitary, asymptomatic, flesh-colored papule or nodule on the face, trunk, or proximal and mid extremities of adults.^{322–325} The nodules average 1 cm in diameter. There has been a report of multiple nodules localized to a ‘palm-wide area’ of the right leg³²⁶ and also a report of multiple lesions in a patient with hypothyroidism, which responded to thyroxine.¹⁰⁸ Digital lesions with the histology of focal mucinosis have been described in scleroderma (see p. 354). It has been reported in association with other cutaneous mucinosis.³²⁷ Oral focal mucinosis is a related condition,³²⁸ and one reported case was associated with cervical external root resorption at the same site.³²⁹ The case reported as ‘reactive pseudotumoral papular mucinosis’ is best regarded as a variant of focal mucinosis.³³⁰

It is thought that increased amounts of hyaluronan are produced by fibroblasts at the expense of the connective tissue elements.³³¹

Histopathology³³¹

There is a slightly elevated or dome-shaped dermal nodule with separation and variable replacement of collagen bundles by mucinous deposits (**Fig. 13.11**). These deposits may be localized to the upper dermis or extend through the full thickness of the dermis. The subcutis is rarely involved.³³² Slit-like spaces occasionally develop. The margins of the mucinous deposition are not sharply demarcated. Spindle-shaped fibroblasts are present within the mucinous areas, and there may be an increase in small blood vessels. The appearances resemble the early stages of a digital mucous cyst (see later) and an individual lesion of papular mucinosis. The material stains with colloidal iron and Alcian blue at pH 2.5 and is metachromatic with toluidine blue at pH 3.0 (**Fig. 13.12**). Immunohistochemistry confirms that the spindle cells are predominantly fibroblasts with some factor XIIIa-positive dendritic cells.³²⁴

Electron microscopy

The fibroblasts have a well-developed rough endoplasmic reticulum. In addition, there are large macrophages and granular and amorphous material representing the mucinous deposits.³²⁶

DIGITAL MUCOUS (MYXOID) CYST

Digital mucous cysts occur as solitary, dome-shaped, shiny, tense cystic nodules on the dorsum of the fingers, usually involving the base of the

Figure 13.10 Scleredema. (A), (B) The collagen bundles are slightly swollen and separated from one another. Cellularity of the dermis is normal with no increase in fibroblasts. (H&E) (C), (D) Mucin deposits are present on the surface of the collagen. (Colloidal iron)

Figure 13.12 Focal mucinosis. The abundant mucin is confirmed with a mucin stain. (Colloidal iron)

nail.³³³ Subungual cases, distal to the nailfold, also occur.³³⁴ Multiple cysts on a single finger have been reported; they were of the ganglionic subtype (see later).³³⁵ The toes are uncommonly involved. The cysts are found in the middle-aged or elderly, and there is a slight female preponderance. A second type, overlying the distal interphalangeal joint, is related to a ganglion because injection studies have demonstrated a connection with the underlying joint cavity.³³⁶ It has been suggested that all digital mucous cysts connect with this joint.³³⁷ Ganglions at other sites are beyond the scope of this book.^{338,339} A superficial angiomyxoma arising on the finger has been reported; it mimicked a digital mucous cyst.³⁴⁰

A skin flap that includes the undersurface of the cyst and the tissues between the cyst and the distal interphalangeal joint, but avoiding removal of the skin itself, has been used successfully in their treatment.³³⁷ A variant of the bilobed flap designed by Zitelli has been recommended as an excellent method for repairing these lesions.³⁴¹ Infrared coagulation has also been used.³⁴²

Histopathology³⁴³

The variant developing at the base of the nail resembles focal mucinosis with a large myxoid area containing stellate fibroblasts, sometimes with microcystic spaces (Fig. 13.13). The overlying epidermis may be thinned by the expanding subepidermal collection of mucus. The mucin stains with the colloidal iron stain, as well as with Alcian blue at pH 2.5, and it is digested by hyaluronidase.³⁴³

The *ganglionic variant* comprises a cystic space with a well-defined fibrous wall of variable thickness and density (Fig. 13.14). There are often small areas of myxoid change adjacent to the wall.³⁴⁴ There may be an attenuated synovial lining.

MUCOCELE OF THE LIP

Mucoceleles (mucous cysts) result from the rupture of a duct of a minor salivary gland with extravasation of mucus into the submucosal tissues, most commonly of the lower lip.³⁴⁵ They may also develop in the buccal mucosa or tongue. Multiple superficial mucoceleles on the lips and oral mucosa have been reported in association with graft-versus-host disease.³⁴⁶ A case reported on the anterior neck was related to the presence of ectopic minor salivary glands.³⁴⁷ Mucoceleles are found mostly in young adults.

Mucoceleles are translucent, whitish or bluish nodules with a firm cystic consistency and vary in size up to 1 cm in diameter. They occasionally rupture spontaneously or after minor trauma.

A superficial variant of mucocele, which results in vesicular lesions that may be mistaken for mucous membrane pemphigoid, has been reported.³⁴⁸ They may be single or multiple, and they arise on non-inflamed mucosa.

Histopathology

Two patterns may be seen, but there may be some overlap between them.³⁴⁵ In one, there is a cystic space with a surrounding poorly defined lining of macrophages, fibroblasts, and capillaries with variable amounts of connective tissue. In the other pattern, there is granulation and fibrous tissue containing mucin-filled spaces with variable numbers of muciphages (Fig. 13.15). Small cystic spaces may be present. Numerous neutrophils and some eosinophils are present in the cystic spaces or stroma of both types. There is no epithelial lining to the cyst, although occasionally a ruptured salivary duct may be seen at one edge of the cyst. Minor salivary gland tissue is present in the adjacent connective tissue.

The mucin is strongly PAS positive and diastase resistant, and it is positive with Alcian blue at pH 2.5 and with colloidal iron.

Superficial mucoceleles are subepithelial, although there may be partial or complete epithelial regeneration across the vesicle floor. They

Figure 13.14 Digital mucous cyst. This is the ganglionic variant. (H&E)

contain sialomucin. Salivary gland ducts are present in the immediate vicinity of the lesions and are a clue to the diagnosis.³⁴⁸

CUTANEOUS MYXOMA AND CARNEY'S COMPLEX

Cutaneous myxomas have been reported in approximately 50% of patients with the complex of cardiac myxomas, spotty pigmentation (lentigines and blue nevi), and endocrine overactivity.³⁴⁹⁻³⁵⁴ This combination of lesions is known as Carney's complex (OMIM 160980), an autosomal dominant condition that has been mapped via linkage analysis to chromosomes 2p16 and 17q2.³⁵⁵ A mutation in the *PRKAR1α* gene on the chromosome 17q22-q24 locus has been identified in patients with Carney's complex, particularly those with atrial myxomas. This gene, which is a tumor-suppressor gene, encodes the R1-α regulatory subunit of cyclic adenosine monophosphate-dependent protein kinase A (PKA).³⁵⁶ The gene located on 2p16 has not yet been identified.

The cutaneous myxomas may be the earliest manifestation of the syndrome.³⁵⁷ They are typically found on the eyelids, nipples and buttocks, and in the external ear canals; they are frequently misdiagnosed

Figure 13.16 Myxoma. There are thin collagen bundles and fibroblasts scattered through a mucinous matrix. (H&E)

as fibroepithelial lesions.³⁵⁸ Spotty pigmented lesions (lentigines and blue nevi) are typically found on the face, specifically along the lips and around the eyes.^{358,359} Similar cases have been reported as the NAME or LAMB syndrome (see Chapter 32, p. 838). Cutaneous emboli from atrial myxomas have also been described.³⁶⁰

Solitary and disseminated myxomas unassociated with any systemic abnormalities may also occur.^{361–365} They are benign neoplasms, but they are included here because of their prominent stromal mucin.³⁶⁶ They are probably the same entity as solitary superficial angiomyxoma (see Chapter 34, p. 1012).

In one reported case, a patient with multiple periorbital myxomas progressed to a scleromyxedema-like dermatosis.³⁶⁷

Histopathology

The tumors are sharply circumscribed, nonencapsulated lesions that may be in the dermis or subcutis. They are composed of a prominent mucinous matrix containing variably shaped fibroblasts, prominent capillaries, mast cells, and a few collagen and reticulin fibers (Fig. 13.16). Sometimes an epithelial component is present, and this may take the form of a keratinous cyst or epithelial strands with trichoblastic features.³⁵¹ These latter changes may mimic the basaloid proliferations sometimes seen above dermatofibromas.³⁶⁸ The lesions differ from focal mucinosis by their vascularity. If the vascular component is marked, the term ‘angiomyxoma’ is often used (see p. 1012).³⁶³ Nerve sheath myxomas are more cellular, often with a distinct patterned arrangement.

The designation ‘fibromyxoma’ has been applied to the lesions in a patient with multiple cutaneous tumors, resembling dermatofibromas clinically but containing more fibroblasts than the usual cutaneous myxomas and some histiocytes, in addition to the interstitial mucin.³⁶⁹ Familial myxovascular fibroma is a morphologically related entity (see p. 972).

Differential diagnosis

The microscopic distinction between focal mucinosis and cutaneous myxoma has not been well delineated. Some consider them variants of a single entity, whereas others treat cutaneous myxoma and superficial angiomyxoma as synonymous terms. The latter interpretation would agree with the findings of Ferreiro and Carney in a study of what they termed myxomas of the external ear in patients with the Carney complex.³⁵¹ In addition to mucin, these lesions featured rich capillary matrices and sometimes a proliferative epithelial component

Figure 13.17 Mucinous nevus. This is an unusual example in which there are focal dermal concentrations of elastic fibers, associated with mucin deposition. (Movat pentachrome)

– features that are also characteristic of superficial angiomyxomas but not expected in focal mucinosis.

NEVUS MUCINOSUS (MUCINOUS NEVUS)

Nevus mucinosus (mucinous nevus) is a variant of connective tissue nevus in which there is a deposition of acid mucopolysaccharides (proteoglycans) in the dermis.^{166,370} The existence of such an entity has been postulated for some time in light of the nevoid lesions of the other connective tissue elements – collagen and elastic tissue. Cases previously reported as cutaneous mucinosis of infancy (discussed previously) may represent examples of nevus mucinosus.

The lesions are small papules, in a grouped, zosteriform or linear arrangement, on the extremities or trunk.^{371–373} They are present at birth or appear in childhood or early adult life.³⁷⁴ A familial case has been reported.³⁷⁵ In another case, a woman had an extensive inflammatory linear verrucous epidermal nevus in addition to nevus mucinosus on the buttock.³⁷⁶

Histopathology

The epidermis usually shows some acanthosis with thin, elongated rete ridges. There is a grossly thickened papillary dermis with an ‘empty appearance’ due to the deposition of abundant acid mucopolysaccharides. The mucinous stroma is strongly stained with hyaluronate-binding protein, indicating the presence of hyaluronate.³⁷⁷ Fibroblasts are slightly increased in number, with occasional stellate forms.¹⁶⁶ Elastic fibers are decreased in the papillary dermis but normal in the deeper dermis.³⁷³ A sparse inflammatory infiltrate composed of lymphocytes and eosinophils may be present in the mid dermis beneath the mucin deposit.³⁷⁷ One case displayed fat cells within upper dermal collagen in addition to papillary dermal mucin deposition.³⁷⁸ We have also seen a variant of mucinous nevus in which there were focal areas of elastic fiber increase in the dermis, forming a ‘checkerboard’ arrangement; mucin deposition in this case appeared to be concentrated in the zones of increased elastic fibers (Fig. 13.17).

Differential diagnosis

The mucin in nevus mucinosus is deposited in the upper dermis, in contrast to papular mucinosis, in which the mucin is at a lower level. Nevus mucinosus differs from acral persistent papular mucinosis on

clinical grounds and also by having fewer fibroblasts within the lesions. Focal mucinosis differs by its larger size and solitary nature.

PROGRESSIVE MUCINOUS HISTIOCYTOSIS

Progressive mucinous histiocytosis (OMIM 142630) – a rare, autosomal dominant histiocytosis of childhood – is characterized by multiple small papules composed of epithelioid and spindle-shaped histiocytes set in abundant stromal mucin. Sporadic cases have been reported.³⁷⁹ This entity is discussed in more detail with the histiocytoses (see p. 1154).

SECONDARY DERMAL MUCINOSES

Mucin deposition may be present in a wide variety of connective tissue diseases and in some tumors. These conditions include dermatomyositis, lupus erythematosus (see later), scleroderma,³⁸⁰ linear morphea,³⁸¹ the toxic oil syndrome, hypertrophic scars, connective tissue nevi, granuloma annulare, malignant atrophic papulosis (Degos' disease), erythema annulare centrifugum, postinflammatory hyperpigmenta-

tion,³⁸² Still's disease,³⁸³ mycosis fungoides,³⁸⁴ and Jessner's lymphocytic infiltrate.^{4,5} Localized mucinosis may follow erysipelas³⁸⁵ or be associated with lower leg edema and morbid obesity.³¹ Mucin is sometimes present in large amounts around the secretory coils of the eccrine glands of the lower leg when sweat excretion is blocked.⁵ Tumors containing mucin include neurofibromas, neurilemmomas, nerve sheath myxomas, chondroid syringomas, and some basal cell carcinomas. A diffuse dermal mucinosis can be found occasionally in biopsies of lesional skin from patients with discoid and systemic lupus erythematosus (SLE).^{386,387} Rarely, patients with SLE and systemic sclerosis can present with papulonodules or plaques due to a diffuse mucinous deposition in the skin (Fig. 13.18).^{380,387-395} In these individuals, the deposition occurs in areas free from specific lesions of lupus erythematosus, and it produces clinically distinct manifestations. A factor (or factors) in the patient's serum appears to stimulate fibroblasts to produce increased amounts of glycosaminoglycan.³⁹¹ Multiple plaques of mucinosis have been reported as the sole manifestation of dermatomyositis in a patient with a nasopharyngeal carcinoma.³⁹⁶ A solitary plaque on the face has been reported in a patient with secondary extramedullary cutaneous plasmacytoma.³⁹⁷

The case reported as 'plaque-like erythema with milia' occurred in a renal transplant recipient on cyclosporine (ciclosporin), which was

Figure 13.18 (A) Lupus mucinosis. (H&E) **(B)** There is wide separation of attenuated collagen bundles by mucin. (Colloidal iron) (Photographs kindly provided by Dr. Geoffrey Strutton.)

implicated in the pathogenesis. There were extensive mucin deposits in the dermis.³⁹⁸

Finally, patients with mitral valve prolapse in which myxomatous degeneration of mitral valve leaflets occurs have been found to have increased cutaneous deposits of proteoglycan (mucin) in the skin.³⁹⁹

FOLLICULAR MUCINOSES

Follicular mucinosis is a tissue reaction pattern in which hair follicles and the attached sebaceous gland accumulate mucin with some dissolution of cellular attachments (Fig. 13.19).³ There is an accompanying perifollicular and perivascular inflammatory cell infiltrate of lymphocytes, histiocytes, and a few eosinophils. Sometimes follicles are converted into cystic cavities with disruption of much of the external root sheath. These cysts contain mucin, inflammatory cells, and keratinous debris. There is often a marked disparity between the amount of follicular mucin and the degree of follicular and perifollicular inflammation.⁴⁰⁰ The material is stained by the Alcian blue and colloidal iron methods. Follicular mucinosis is sometimes seen in arthropod bite

Figure 13.19 Follicular mucinosis. The accumulation of mucin within the hair follicle has resulted in the dissolution of many cellular attachments. (H&E)

reactions and in the exaggerated bite reactions that occur in some patients with chronic lymphocytic leukemia⁴⁰¹ (see secondary follicular mucinosis, discussed later).

The concept that follicular mucinosis is a tissue reaction pattern and not a disease sui generis is a relatively recent one;³ consequently, most reports in the literature use the term 'follicular mucinosis' for what Pinkus described as alopecia mucinosa in 1957.⁴⁰²

FOLLICULAR MUCINOSIS (ALOPECIA MUCINOSA)

Follicular mucinosis (alopecia mucinosa) is an uncommon inflammatory dermatosis with a predilection for adults in the third and fourth decades of life.⁴⁰³ A congenital case has been reported,⁴⁰⁴ as have cases in children. In 11 patients reported in a review from the Mayo Clinic (ages 11–19 years), 3 had mycosis fungoides and 2 had positive T-cell receptor gene rearrangements.⁴⁰⁵ Three clinical types have traditionally been recognized:^{406,407} a benign transient form with one or several plaques or grouped follicular papules, usually limited to the face or scalp and with accompanying alopecia,^{408–413} a more widely distributed form with follicular papules, plaques, and nodules on the extremities, face, and trunk and a course often exceeding 2 years;⁴¹⁴ and a third group, accounting for 15–30% of cases, with widespread lesions and associated with malignant lymphoma of the skin or mycosis fungoides.^{415–419} Rarely, patients with leukemia cutis,⁴²⁰ leukemia without skin lesions,⁴²¹ Hodgkin's disease,⁴²² familial reticuloendotheliosis,⁴²³ Sézary syndrome,^{424,425} squamous cell carcinoma of the tongue,⁴²⁶ and angiolymphoid hyperplasia^{427,428} have also had this presentation. This third group was regarded by Hempstead and Ackerman³ as belonging to the group of secondary follicular mucinosis because of the lack, at that time, of convincing examples of follicular mucinosis (alopecia mucinosa) progressing to mycosis fungoides or cutaneous lymphoma.^{429,430} However, cases of follicular mucinosis progressing to mycosis fungoides have since been well documented.^{431,432} A study of T-cell clonality in follicular mucinosis has shown a monoclonal T-cell population in all patients with associated cutaneous T-cell lymphoma and also in 9 of 16 patients with the primary form of the disease.⁴³³ In another series of 4 cases, presenting as an acneiform eruption of the face in early adulthood, 2 cases demonstrated a clonal rearrangement of the T-cell receptor within the cutaneous infiltrate.⁴³⁴ A study from Graz, Austria, has also cast doubt on the validity of the continued separation of the so-called 'primary form' of follicular mucinosis from the lymphoma-associated group. Not only was there some clinical overlap between the two groups but also histopathological examination did not allow differentiation of the two groups.^{435,436} Furthermore, a monoclonal rearrangement of the TCR gene was demonstrated by polymerase chain reaction analysis in 4 of 10 cases from the primary group and 7 of 17 cases from the lymphoma-associated group.⁴³⁵ These authors postulate that even the primary form of follicular mucinosis may be a form of localized cutaneous T-cell lymphoma.^{435,437} These cases raise the question: when does follicular mucinosis become mycosis fungoides?^{438,439} Ackerman and colleagues have also proposed that **alopecia mucinosa is mycosis fungoides**.^{440,441} Contrary views still exist.⁴⁴² LeBoit challenged the view that there are only two choices – inflammatory disease or mycosis fungoides – for the pathogenesis of follicular mucinosis (alopecia mucinosa). He has raised the possibility that its lesions are 'an expression of a self-limited proliferation of lymphocytes, e.g. a benign neoplasm of them'.⁴⁴³ He also notes that lymphocytic infiltrates are the only ones in which clonality has been used to infer malignancy.⁴⁴³ Guitart and Magro included idiopathic follicular mucinosis in their classification of *cutaneous T-cell lymphoid dyscrasias*, a unifying term for idiopathic chronic dermatoses with persistent T-cell clones.⁴⁴⁴ This is another 'third choice' and the one favored by the author of this book. Follicular mucinosis has also been seen in skin lesions of adult T-cell leukemia/lymphoma⁴⁴⁵

Figure 13.20 Follicular mucinosis (alopecia mucinosa). Multiple follicles show the reaction pattern of follicular mucinosis. (H&E)

and primary cutaneous, eosinophil-rich CD30⁺ anaplastic large cell lymphoma.⁴⁴⁶

The protean clinical presentations attributed to follicular mucinosis, such as eczematous,⁴⁴⁷ annular, pityriasis rosea-like,⁴⁴⁸ and folliculitis, are in many cases examples of specific dermatoses in which secondary follicular mucinosis is present.

Primary follicular mucinosis has been successfully treated with photodynamic therapy.⁴⁴⁹

Histopathology^{407,450,451}

Although it has been postulated that follicular keratinocytes are the source of the mucopolysaccharides that accumulate within follicular epithelia (Fig. 13.20),^{3,452} this has not been confirmed in another study, which proposed a role for cell-mediated immune mechanisms in the etiology.⁴³⁰ A recent study found active secretion of hyaluronate by follicular keratinocytes in follicular mucinosis, but CD44 expression (a cell-surface receptor of hyaluronate) was not increased.⁴⁵³ In a study published in 2010, a proportion of cases of follicular mucinosis (24% of primary follicular mucinosis and 10% of lymphoma-associated follicular mucinosis) showed sulfated mucin in addition to hyaluronate in the involved follicles, indicated by positive staining with Alcian blue at pH 2.5 and 0.5.⁴⁵⁴ The inflammatory cell infiltrate is predominantly follicular, perifollicular, and perivascular in location, in contrast to the follicular mucinosis secondary to lymphomas, in which the infiltrate is more dispersed, often heavier and nodular, and sometimes has more plasma cells and fewer eosinophils than in primary follicular mucinosis.⁴⁰⁰ Even the follicular mucinosis of mycosis fungoides can have an unimpressive infiltrate, composed of small lymphocytes with minimal atypia.⁴⁵⁵ Furthermore, there is usually a milder mucinous change in follicular mucinosis related to lymphomas than in primary follicular mucinosis. However, as mentioned previously, the study from Graz casts doubt on the validity of separating the primary form from the lymphoma-associated group,⁴³⁵ and this is further supported by the study of Rongioletti *et al.*⁴⁵⁴ Atypical cells and Pautrier microabscesses are not seen in follicular mucinosis,⁴⁰⁰ but they may be present in secondary follicular mucinosis with accompanying lymphoma or mycosis fungoides. Rarely, dermal mucinosis^{422,456} or a proliferation of eccrine sweat duct epithelium is present.⁴⁵⁷ The term **folliculotropic T-cell lymphocytosis** has been proposed for a case that clinically resembled follicular mucinosis but in which there were minimal mucin deposits in the hair follicles.⁴⁵⁸

Electron microscopy

Electron microscopy shows disattached keratinocytes closely opposed to significant numbers of macrophages and Langerhans cells.⁴³⁰ Some degeneration of keratinocytes has also been noted.^{452,459} Fine granular and flocculent material is present between the keratinocytes.

SECONDARY FOLLICULAR MUCINOSES

Follicular mucinosis may be found as an incidental phenomenon in rare cases of lichen simplex chronicus, hypertrophic lichen planus, discoid lupus erythematosus, SLE,⁴⁶⁰ acne vulgaris, pseudolymphoma, nevocellular nevi,⁴⁶¹ arthropod bite reactions,³ squamous cell carcinoma, seborrheic keratosis, prurigo simplex, polymorphic light eruption, drug-related vasculitis, demodicidosis, and dextromethorphan-induced phototoxicity.⁴⁶² Other cases associated with the ingestion of various drugs, such as calcium channel blockers, β -blockers, antihistamines, antidepressants, and imatinib, have been reported.⁴⁶³ Follicular mucinosis has been associated with a mycosis-fungoides-like hypersensitivity syndrome due to oxcarbamazepine⁴⁶⁴ and a mycosis fungoides-like drug eruption due to the gonadotropin-releasing hormone agonist leuprolide.⁴⁶⁵ The superficial follicular spongiosis seen in some cases of atopic dermatitis, Grover's disease, and actinic prurigo,⁴⁶⁶ as well as in infundibulofolliculitis, may contain small amounts of mucin.⁴⁶⁷ A hair follicle nevus distributed along Blaschko's lines was noted to have mucin deposition exclusively within the epithelia of involved follicles; the authors termed this lesion 'nevroid follicular mucinosis'.⁴⁶⁸ Mir-Bonafe *et al.* noted the potential role of ultraviolet-induced dermatoses in the production of many examples of secondary follicular mucinosis.⁴⁶² The follicular mucinosis sometimes associated with eosinophilic folliculitis, particularly in cases associated with HIV infection, is discussed in Chapter 15.

Differential diagnosis

Follicular mucinosis is a rather distinctive microscopic finding, and lesions with extensive intrafollicular mucin, including microcyst formation, are difficult to confuse with any other process. However, more subtle changes could resemble forms of spongiotic folliculitis as can be seen in eczematous dermatoses (e.g., atopic dermatitis). On the other hand, the characteristic thread-like, gray mucinous material is not observed in spongiotic folliculitis, and special stains show minimal, if any, intrafollicular mucin in those cases. The secondary follicular mucinosis seen incidentally in other inflammatory dermatoses tends to show smaller quantities of intrafollicular mucin, without the formation of large cystic spaces; other histopathologic changes may point to a different diagnosis, such as lupus erythematosus, a photodermatosis, or one of the other conditions listed previously. As mentioned, a reliable histopathologic distinction between benign follicular mucinosis and lymphoma-associated follicular mucinosis is generally not possible.

PERIFOLLICULAR MUCINOSIS

There is one report of an adolescent male who developed two plaques on the face characterized by prominent perifollicular mucin. The lesions were regarded as being of nevroid origin.⁴⁶⁹ Perifollicular mucinosis has also been reported in a patient with HIV infection and an atypical pityriasis rubra pilaris-like eruption.⁴⁷⁰

EPITHELIAL MUCINOSES

Small foci of intercellular mucin are an inconstant and incidental finding in some spongiotic dermatoses, as well as in verrucae,

seborrheic keratoses, basal cell and squamous cell carcinomas, and keratoacanthomas.³ Epidermal mucin is sometimes a conspicuous feature in mycosis fungoides (see p. 1177).

Eccrine ductal mucinosis, in which there was mucin between the cells of the outer layer of the eccrine duct, has been reported in a patient with HIV infection and probable scabies. The significance of these related conditions and the nature of the mucinosis remain an enigma.⁴⁷¹

MUCOPOLYSACCHARIDOSES

The mucopolysaccharidoses are a group of 10 lysosomal storage diseases that result from the deficiency of specific lysosomal enzymes involved in the degradation of dermatan sulfate, heparan sulfate, or keratan sulfate, singly or in combination.⁴⁷²⁻⁴⁷⁴ As a consequence, mucopolysaccharides accumulate in various tissues and are excreted in the urine.⁴⁷⁵ Because of genetic variability, heterogeneity, and pleiotropism, more than 10 clinical syndromes are associated with the 10 enzyme deficiencies.⁴⁷²

The specific enzyme defect can be identified using cultured fibroblasts, although in many instances a tentative diagnosis is possible on the clinical features alone. Prenatal diagnosis is possible on both cultured amniotic fluid cells and chorionic villus samples. Analysis of the urine for certain mucopolysaccharides will also assist in the diagnosis. The urine contains heparan sulfate in the Sanfilippo syndrome (MPS III, OMIM 252900), keratan sulfate in the Morquio syndrome (MPS IV, OMIM 253000), dermatan sulfate in the Maroteaux-Lamy syndrome (MPS VI, OMIM 253200), and an excess of dermatan and heparan sulfates in varying ratios in the others.

The mucopolysaccharidoses share many clinical features,⁴⁷² including skeletal abnormalities characterized as dysostosis multiplex (except in Morquio's syndrome), short stature (excluding Scheie's syndrome; MPS IS, OMIM 607016), corneal clouding (except in the Hunter (MPS II) and Sanfilippo (MPS III) syndromes), deafness, grotesque facies (gargoylism), hirsutism, premature arteriosclerosis, hepatosplenomegaly, and severe mental retardation (excluding MPS VI and MPS IS).⁴⁷² The best known of the mucopolysaccharidoses are Hurler's syndrome (MPS I, OMIM 607014), which has the worst prognosis and is due to a deficiency of α -L-iduronidase encoded by the *IDUA* gene at 4p16.3,⁴⁷⁶ and Hunter's syndrome (MPS II, OMIM 309900), which results from a deficiency of iduronate-2-sulfatase. Hunter's syndrome is the only X-linked mucopolysaccharidosis with the gene defect located at Xq28.^{477,478} The genetic defect in Sanfilippo syndrome type A (OMIM 252900) is situated on chromosome 17q25.3. Numerous different mutations have been identified.⁴⁷⁹ The transmembrane protein 76 gene (*TMEM76*) has been identified as a possible cause of Sanfilippo syndrome type C (OMIM 252930), a disorder of heparan sulfate degradation due to a deficiency of the enzyme *N*-acetyltransferase.⁴⁸⁰ Other publications attribute this variant to mutations in the *HGSNAT* gene.

Cutaneous manifestations of the mucopolysaccharidoses include hirsutism and dryness of the skin. There may also be mild thickening; this is most marked in Hurler's syndrome, in which sclerodermoid thickening of the fingers and furrowing of the skin can occur.^{481,482} Firm, flesh-colored to waxy papules and nodules can be found on the upper trunk, particularly in the scapular region, in Hunter's syndrome.^{477,483-486} They give rise to a characteristic cobblestone appearance.⁴⁸⁷ These papules disappear after a hemopoietic stem cell transplant.⁴⁸⁸ Extensive Mongolian spots are another manifestation of Hunter's syndrome.^{489,490}

Figure 13.21 Hunter's syndrome. Considerable interstitial mucin deposition is present in the lower dermis, from a papular lesion. (H&E)

Allogeneic bone marrow transplantation before the age of 2 years will halt disease progression in Hurler's syndrome. A recombinant human α -L-iduronidase has been given intravenously to patients with this deficiency.

Histopathology

Metachromatic granules are present in the cytoplasm of fibroblasts in all cases and are sometimes seen in eccrine sweat glands and epidermal keratinocytes.⁴⁸¹ Metachromatic granules were absent in one case, but the large amount of extracellular mucin may have obscured their recognition.⁴⁸⁷ Extracellular mucin of any significant amount is only found in the mid and lower dermis in the papulonodules of Hunter's syndrome (Fig. 13.21).⁴⁸³ There are widely separated collagen bundles in the dermis with intervening pale blue, fibrillar material.⁴⁷⁸ This mucin can be seen in toluidine blue-stained sections of alcohol-fixed material, but it can also be demonstrated with the Giemsa, Alcian blue, and colloidal iron stains.^{478,483} The fibroblasts are slightly more prominent than usual with an oval nucleus and a definable cytoplasmic outline, but these changes are quite subtle.

Electron microscopy

The ultrastructural features are characteristic with multiple membrane-bound vacuoles, containing some amorphous and granular material, within the cytoplasm of fibroblasts.^{491,492} Vacuoles are also present, to a variable extent, in endothelial cells, Schwann cells,⁴⁹¹ mononuclear cells,⁴⁹³ and eccrine glands.⁴⁹⁴ Lamellar inclusions are sometimes observed, particularly in Schwann cells.^{495,496} A single large vacuole, indenting the nucleus of keratinocytes, has been seen in some cases.⁴⁹⁷ Vacuoles may develop in some cells as an artifact of fixation; these should not be misinterpreted as features of a mucopolysaccharidosis.⁴⁹⁸

INTRODUCTION

Cutaneous deposits are a heterogeneous group of substances that are not normal constituents of the skin. They are laid down, usually in the dermis, in a variety of different circumstances. There are five broad categories of deposits (Table 14.1). The first group includes calcium salts, bone, and cartilage.¹ The second category includes the hyaline deposits. These have an eosinophilic, somewhat glassy appearance in hematoxylin and eosin (H&E) preparations. The third category includes various pigments, heavy metals (many of which are deposited in the form of a pigmented salt), and complex drug pigments. The fourth category, cutaneous implants, includes substances such as collagen and silicone that are inserted into the skin for cosmetic purposes. The fifth category includes miscellaneous substances such as oxalate crystals and fiberglass.

Some deposits evoke an inflammatory or foreign body reaction, although many of the hyaline and pigment deposits produce no significant response, except for some macrophages in the case of pigments. Hyaline deposits may blend imperceptibly with the surrounding collagen and require special histochemical staining for their positive identification.

CALCIUM, BONE, AND CARTILAGE

CALCINOSIS CUTIS

The cutaneous deposition of calcium salts – calcinosis cutis – has historically been divided into a dystrophic variety, when the calcium is deposited in damaged or degenerate tissue, and a less common metastatic form associated with elevated serum levels of calcium or phosphate or both.^{2,3} In many cases, the pathogenetic mechanism is unknown, and these have been assigned to a third idiopathic group. Sometimes, several mechanisms are involved in the formation of the calcium deposits.^{4,5} Rarely, no satisfactory explanation can be advanced for the calcium deposition.⁶ A study of idiopathic cases of calcification and ossification of the skin found that bone morphogenetic protein 4, β -catenin, osteopontin, osteonectin, and osteocalcin were involved in the process;⁷ it is a highly regulated one. The following classification is a modification of the historic one.¹

Subepidermal calcified nodule

Subepidermal calcified nodule usually occurs as a solitary nodule on the head, particularly the ear, or the extremities of infants and young children, with locations including the sole of the foot,^{8,9} but it may develop in an older group of patients in whom it has a predilection for the upper extremities.^{10–17} Multiple lesions have been reported on the eyelids.¹⁸ Mucosal lesions are rare.¹⁹ Subepidermal calcified nodule is one of the idiopathic calcinosises, although it has been suggested that the calcification occurs in a pre-existing nevus or hamartoma.²⁰ There is little evidence to support this view. It has been suggested that congenital lesions occurring on the ear should be categorized as a variant

of traumatic calcinosis cutis because of presumptive *in utero* micro-trauma; the term **congenital calcinosis cutis of the ear** has also been suggested for these cases.^{21,22}

Idiopathic scrotal calcinosis

Single or multiple lesions, up to 3 cm or more in diameter, develop in the scrotal skin in children or young adults.^{23–29} They may break down and discharge chalky material. It has been suggested that the lesions represent dystrophic calcification of eccrine duct milia³⁰ or of epidermal cysts,^{26,31,32} although this has been disputed.^{33–35} A study of 20 cases concluded that scrotal calcinosis results from calcification of hair follicular or epidermal cysts, but this epithelium eventually disappears and may not be seen.³⁶ Calcification of degenerate dartoic muscle has also been suggested as a cause.³⁷

A similar process involving the vulva and penis has been reported.^{38–41}

Tumoral calcinosis

Tumoral calcinosis is characterized by the presence of large, often multiple deposits of calcium hydroxyapatite that preferentially involve periarticular soft tissue on the extensor aspect of large joints.^{42–47} There is a predilection for black races. Cases involving the small joints of the hand have been described.^{46,48} In the large series of 43 cases of the distal extremities, mainly from the Armed Forces Institute of Pathology (AFIP), various predisposing conditions were identified, including hyperphosphatemia, scleroderma, osteoarthritis, renal failure, and congenital deformities.⁴⁶ The etiology was indeterminate in many cases.⁴⁶

Familial cases also occur.⁴⁹ Familial tumoral calcinosis (OMIM 211900) is an autosomal recessive disorder caused by hyperphosphatemia secondary to the increased renal reabsorption of phosphate. Mutations in the GalNac-transferase-3 gene (*GALNT3*) on chromosome 2q24–q31 have been described.^{50–52} The gene product is considered important in the structure and function of the phosphaturic hormone fibroblast growth factor-23 protein (FGF23), deficiencies of which have also been associated with familial tumoral calcinosis.⁵² The *FGF23* gene maps to 12p13.3. Four novel mutations in the *GALNT3* gene have been identified in patients with tumoral calcinosis and hyperostosis–hyperphosphatemia syndrome, supporting the concept that these two conditions are variant forms of the same disease with different manifestations (respectively, massive calcifications and cortical hyperostosis). The authors of this study proposed the umbrella term familial hyperphosphatemic tumoral calcinosis for these disorders.⁵³ A normophosphatemic variant of familial tumoral calcinosis (OMIM 610455) has been described in which cutaneous calcification is preceded by severe inflammation. It is due to a mutation in *SAMD9*, resulting in deficiency of the associated, interferon- γ and tumor necrosis factor- α -responsive protein. Ordinarily, this functional *SAMD9* protein interacts with Ral guanine nucleotide dissociation stimulator-like 2 protein (RGL2) to reduce the expression of *EGR1*, a transcription factor involved in the pathogenesis of ectopic calcification, inflammation, and cell migration.⁵⁴

Several studies have now indicated that there may be preceding fibrohistiocytic and cystic nodules, prior to the deposition of any calcium salts.^{46,55,56}

Auricular calcinosis

Auricular calcinosis is a rare lesion of one or both ears that may be secondary to local factors such as inflammation, frost bite, or trauma or be associated with systemic diseases such as Addison's disease, ochronosis, or hypopituitarism.^{57,58} It involves calcification of the auricular cartilage. The term 'petrified ear' is sometimes used.^{59–62}

Table 14.1 Categories of cutaneous deposits

Calcium salts, bone, and cartilage
Hyaline deposits
Pigments, heavy metals, drug pigments
Cutaneous implants
Miscellaneous deposits

Ossification rarely develops in auricular calcinosis.⁶³ This lesion is different from the calcified nodule that is present at birth and called congenital calcinosis cutis of the ear (discussed previously), which does not involve the cartilage.

Infantile calcinosis of the heel

Calcinosis of the heel has been reported in infants who received multiple heel pricks for blood tests.^{64,65} It has also been reported after a solitary episode.⁶⁶ The deposits have been recognized at 10–12 months of age, and they disappear approximately 1 year later. This group should probably be regarded as a clinical variant of dystrophic calcification; the nature of the underlying damage to the dermis that leads to the deposition of the calcium salts has not been elucidated.

Milia-like calcinosis

There have been several reports of children with pinhead-sized nodules, usually in the genital area, thighs, or knees, that disappear spontaneously.^{67,68} Some cases recur a few weeks later.^{69,70} This milia-like pattern of calcification may occur with Down syndrome.^{71–75}

Dystrophic calcification

In dystrophic calcification, there may be widespread large deposits (calcinosis universalis), such as occur in dermatomyositis^{76–78} and rarely in lupus erythematosus,^{79–85} and porphyria cutanea tarda,⁸⁶ or a few small deposits (calcinosis circumscripta), as seen in scleroderma^{87–89} (see p. 348). Calcinosis cutis universalis has also been reported as an idiopathic phenomenon in the absence of any underlying disease or altered calcium/phosphate levels.⁹⁰ Also included in the dystrophic group¹ are the calcium deposits that are found, rarely, in burns scars, keloids, acne scars, trauma sites,^{91,92} venous ulcers,⁹³ radiation sites,⁹⁴ injection sites,^{95–99} a violin pressure point,¹⁰⁰ and following calcium chloride or gluconate burns or infusions^{101–108} and the use of calcium chloride-containing electrode pastes for electroencephalograms.^{109–111} The injection of calcium-containing heparins in patients with chronic renal failure may also result in calcinosis cutis at the injection sites.^{112,113} Cutaneous calcification of dystrophic type may follow the percutaneous penetration of calcium salts in those exposed to industrial drilling fluids containing calcium salts.¹⁰⁹ It has also been reported following neonatal herpes simplex infection¹¹⁴ and in patients with the Ehlers–Danlos syndrome (see p. 376). Widespread cutaneous calcification has been reported in pseudoxanthoma elasticum.¹¹⁵ The disseminated linear lesions of calcinosis cutis that developed in an infant with congenital acute monocytic leukemia were regarded as dystrophic lesions that occurred secondary to koebnerization from scratching.¹¹⁶ The dystrophic calcification of the CREST syndrome has responded to treatment with intravenous immunoglobulin.¹¹⁷

Metastatic calcification

Cutaneous involvement is a rare manifestation of the metastatic calcification that may accompany the hypercalcemia associated with primary or secondary hyperparathyroidism, destructive lesions of bone,¹¹⁸ hypervitaminosis D, and other rare causes.^{5,119,120} It is usually a late complication of chronic renal failure.¹²¹ The deposits are found in the deep dermis or subcutaneous tissue, particularly in the axillae, abdomen, medial aspect of the thighs, the vulva, and the flexural areas.^{122–124} The cutaneous calcification seen in some patients after liver transplantation is probably of metastatic type due to the large amounts of intravenous calcium needed to correct hypocalcemia following the use of blood products.^{125,126} A similar etiology may have resulted in the

calcinosis cutis that developed in a patient with cystic fibrosis after double lung transplants.¹²⁷

Calciophylaxis

Calciophylaxis (calcific uremic arteriolopathy) is an uncommon and often lethal variant of metastatic calcification in which calcification of the walls of small to medium-sized vessels in the dermis and subcutis induces ischemic necrosis of the skin.^{128–137} The incidence is 4.5 per 1 million persons.¹³⁸ Its prevalence in patients on hemodialysis is 4.1%. Most cases occur in the elderly; childhood cases are uncommon.¹³⁹

It presents as painful livedo reticularis and tender erythematous plaques or nodules on the buttocks, abdomen, breasts, and the upper and lower extremities.^{140,141} A net-like pattern of calcification on plain radiographs is strongly associated with calciophylaxis, with a specificity that approaches 90%.¹⁴² The lesions may become necrotic and ulcerate.^{134,143} The penis is a rare site of involvement.¹⁴⁴

Most cases of calciophylaxis are associated with end-stage renal failure with secondary hyperparathyroidism,^{145,146} but it has also been associated with hypoalbuminemia,¹⁴⁷ primary hyperparathyroidism,^{148,149} metastatic breast carcinoma,^{150,151} presumptive functional protein C and protein S deficiency induced by chemotherapy,¹⁵² alcoholic cirrhosis,^{136,153} warfarin therapy in a diabetic patient,¹⁵⁴ and vitamin K therapy.¹⁵⁵ In fact, a review of the literature suggests a role for a hypercoagulable state in the pathogenesis of calciophylaxis.¹⁵⁶ Several examples have been reported in patients with POEMS syndrome; a possible explanation is the frequently elevated levels of vascular endothelial growth factor (VEGF), which is an activator of the coagulation pathway.¹⁵⁷ An idiopathic case has also been reported.¹⁵⁸ Obesity and systemic corticosteroids are risk factors for the development of calciophylaxis.¹⁵⁹

The pathogenesis of calciophylaxis is now being elucidated.¹⁶⁰ Work suggests that activation of the NF-κB pathway plays an important role. Accordingly, inhibitors of the RANKL–RANK–NF-κB pathway such as bisphosphonates, recombinant osteoprotegerin, and anti-RANKL antibodies may theoretically assist in the treatment of calciophylaxis.¹⁶⁰

The mortality rate is 60–80%, and this is related to wound infection, sepsis, and organ failure.¹⁴¹ Surgical debridement is associated with improved survival.¹⁵⁹ Other treatments that have been used include cinacalcet,¹⁶¹ sodium thiosulfate,^{162–165} pamidronate,¹⁶⁶ other bisphosphonates,¹⁶⁷ and low-dose tissue plasminogen activator.¹⁶⁸

Calcification of blood vessels

Calcification may involve blood vessels in the skin in metastatic and in dystrophic calcification.¹⁶⁹ It may be associated with cutaneous necrosis, particularly in calciophylaxis.^{170–172}

Calcification of cysts and neoplasms

Calcification may occur in trichilemmal cysts, pilomatrixomas, trichoepitheliomas, syringomas,¹⁷³ basal cell carcinomas, and hemangiomas.¹ It is dystrophic in type. Although nanobacteria species have been implicated in the pathogenesis of urinary calculi and calcific atherosclerosis, they could not be detected in the calcification seen in tumors or tumoral calcinosis.¹⁷⁴

Histopathology

Calcium salts are easily recognized in H&E sections by their intense, uniform basophilia; if necessary, their nature may be confirmed by von Kossa's silver stain, which blackens the deposits. The subcutaneous deposits found in tumoral calcinosis (Fig. 14.1) and foci of metastatic and dystrophic calcification tend to be large and dense, whereas those found in the dermis, as in subepidermal calcified nodule, are multiple,

Figure 14.1 (A) Tumoral calcinosis. (B) The calcium deposits are large and irregular in shape. (H&E)

small and globular in type (Fig. 14.2). Scrotal deposits are more or less amorphous masses (Fig. 14.3). In a detailed study of 100 cases, a progression of changes was noted from intact epithelial cysts to inflamed cysts with luminal calcific material, inflamed calcified cysts with partial epithelial linings, and ‘naked’ dermal calcium deposits, sometimes with compression of surrounding collagen bundles.¹⁷⁵ In subepidermal calcified nodule and in milia-like calcinosis, there is often overlying pseudoepitheliomatous hyperplasia, associated with transepidermal elimination of some granules.¹⁷⁶ Transepidermal elimination of calcium deposits is uncommon in the other forms.¹²⁰ Foreign body giant cells and peripheral condensation of connective tissue are other features often associated with the deposition of calcium salts. Chronic inflammation is mild or absent.

In familial tumoral calcinosis, the initial phase is characterized by edema, collagen degeneration, mucin deposits, and hyalinization with necrosis and cyst formation. The cystic cavities are lined by osteoclast-like giant cells and mononuclear cells. Calcification then occurs, suggesting that it is a delayed response to tissue injury.⁵⁶ Furthermore, adjacent normal skin does not show any calcium deposits, which might be expected if calcification is the primary event.^{56,177} Similar stages of evolution have been reported in 43 cases of tumoral calcinosis-like

lesions of the distal extremities in which the deposits were smaller and the etiology was varied but not familial.⁴⁶

Biopsy of milia-like calcinosis shows discrete nodular foci of calcification, supportable with positive von Kossa staining. In some examples, these foci are surrounded by a lining that resembles a thin layer of epithelium; in one study, this layer was negative for epithelial membrane antigen,¹⁷⁸ whereas in another the thin luminal surface was EMA positive.¹⁷⁹ Transepidermal elimination of calcified material can occur,¹⁷⁸ and in a case of subcorneal milia-like idiopathic calcinosis cutis, the nodular focus of calcification was found within the epidermis, surrounded by a thin ‘fibrous’ rim.¹⁸⁰ Epidermal and follicular calcification has been reported in the necrotic epithelium associated with toxic epidermal necrolysis in a patient who also had secondary hyperparathyroidism.¹⁸¹ No dermal deposits of calcium were present.

In calciophylaxis, there is usually epidermal ulceration, focal dermal necrosis, and vascular calcification.¹⁸² The calcification involves small to medium-sized vessels particularly in the subcutis (Fig. 14.4A). Because subtle calcification can be missed on H&E-stained sections, special stains using von Kossa and alizarin red can be particularly helpful; at times, either one of these may be negative for calcium while the other is positive, so performance of both stains may be

Figure 14.2 Subepidermal calcified nodule. The calcium deposits are small and globular. (H&E)

worthwhile in these circumstances.¹⁸³ Perieccrine calcification (in the basement membrane surrounding eccrine coils) appeared in one study to be highly specific for calciphylaxis and may be the only form of calcium deposition in a minority of cases.¹⁸³ Fibrin thrombi may be present in capillaries.¹⁵¹ Osteopontin levels are increased at sites of calcium deposition.¹⁸⁴ An acute and chronic calcifying panniculitis is a common finding (Figs. 14.4B and 14.4C).¹⁸⁵ Fat necrosis is often present. Diffuse dermal angiomatosis occasionally accompanies calciphylaxis, possibly representing an early stage of the process. It has been postulated that low-grade ischemia results in increased levels of VEGF and consequent extravascular proliferation of endothelial cells.¹⁸⁶ Several examples of calciphylaxis have shown changes of pseudoxanthoma elasticum in biopsy specimens. The findings were seen in two patients with end-stage renal disease on hemodialysis, but they were also seen in a patient who did not have end-stage renal disease.¹⁸⁷ In this case, alcoholic liver disease was considered a possible cause of the calciphylaxis; the explanation for the pseudoxanthoma elasticum-like changes was not entirely clear because there were no clinical features of that disease, but the possibility of a heterozygote carrier state of an *ABCC6* gene mutation was considered.¹⁸⁷ Calciphylaxis is often overdiagnosed on the basis of a small amount of calcification in small vessels in the

subcutis. This is often just a manifestation of Monckeberg's sclerosis in elderly patients.

Dermoscopy of a case of milia-like calcinosis, in a child with Down syndrome, showed round, smooth, bright white homogeneous lesions, with a petaloid pattern on polarized dermoscopy.¹⁸⁸

Differential diagnosis

Calcium deposits are usually recognizable in routinely stained sections, and therefore special staining is often not necessary. However, there are occasions when such staining may be indicated. An example is the occasional foci of small, rounded, lightly staining calcium deposits that at first glance can resemble fungal spores or yeast forms. The variable size of calcium bodies, their homogeneous appearance, and their basophilia should normally suggest calcium deposition, but this can be confirmed by staining with the von Kossa method (calcium salts stain black or brownish-black) or with alizarin red. Von Kossa staining is also useful in identifying the short, gnarled elastic fibers of pseudoxanthoma elasticum, in which calcification is more subtle. The finding of tumoral calcinosis requires more detailed clinical and laboratory evaluation to determine the underlying cause. The same is true for vascular calcification, although many of these cases are associated with chronic renal failure and abnormal calcium phosphate metabolism. One exception is Monckeberg's medial sclerosis, a form of arteriosclerosis that features calcific deposits in the media of muscular arteries but no intimal involvement; therefore, this finding per se is of limited clinical consequence. Vessels showing this change are often encountered in the subcutis of larger, deeper skin biopsy specimens. The calcium oxalate deposits of oxalosis have a refractile, crystalline appearance that is generally not confused with ordinary calcification, although differential staining using alizarin red can be used to distinguish between the two (see later).

CUTANEOUS OSSIFICATION

Cutaneous ossification has traditionally been classified into a primary form (osteoma cutis), in which there is an absence of a pre-existing or associated lesion, and a secondary type (metaplastic ossification), in which ossification develops in association with or secondary to a wide range of inflammatory, traumatic, and neoplastic processes.^{3,189} There are several distinct clinical variants within the traditional primary group and several syndromes associated with cutaneous ossification. For this reason, the following classification is suggested to cover all circumstances in which bone is found in the skin.

Multiple osteomas

In this variant, multiple foci of cutaneous ossification are present at birth or develop in childhood.¹⁹⁰⁻¹⁹⁴ A family history is sometimes present.^{190,193} Albright's hereditary osteodystrophy should be excluded. An acquired, late-onset variant is mentioned in the literature.^{195,196}

Multiple miliary osteomas of the face

Although there is usually a history of previous acne and/or dermabrasion of the face,¹⁹⁷⁻²⁰³ it appears that multiple miliary osteomas of the face may be found as a true primary condition.²⁰⁴⁻²⁰⁶ Multiple, hard, flesh-colored papules, a few millimeters in diameter, develop on the face.

Auricular ossificans

Auricular ossificans (ectopic ossification of the auricle) is a rare condition that may be unilateral or bilateral. It can be associated with local trauma,²⁰⁷ inflammation, or systemic diseases. It is usually distinguished

Figure 14.3 (A) Idiopathic scrotal calcinosis. (B) The deposits are surrounded by hyaline fibrous tissue. (H&E)

from secondary ossification of auricular calcinosis (discussed previously). Although the bone may involve the cartilage solely,²⁰⁸ it may also be confined to the soft tissue of the ear.²⁰⁹ Cold injury is a frequent predisposing factor to the ossification.^{208,209} It has also been associated with pseudopseudohypoparathyroidism.²¹⁰

Osteomas of the distal extremities

Included in the osteomas of the distal extremities are the subungual exostoses, which are basically cartilage derived, and a rare group of bony tumors of the digits in which no cartilage or bony connection can be demonstrated.

Albright's hereditary osteodystrophy

Cutaneous ossification at an early age may be a presenting feature of Albright's hereditary osteodystrophy (OMIM 103580), which includes the clinical designations of pseudohypoparathyroidism and pseudopseudohypoparathyroidism.^{211–216} The basic abnormality is a defect in tissue responsiveness to parathormone. Hypocalcemia may be present in some cases (pseudohypoparathyroidism type 1a).²¹⁷

Mutations in the *GNAS1* gene on chromosome 20q13 have been implicated. The gene is one of a small number responsible for differences in gene expression between the maternal and paternal alleles, a phenomenon known as imprinting.²¹⁸ Maternal transmission of the mutated gene leads to pseudohypoparathyroidism type 1a, whereas paternal transmission results in Albright's hereditary osteodystrophy.^{218,219} Defects in the same gene (also paternal transmission) are responsible for progressive osseous heteroplasia (see later). In addition to the ossification of dermal, subcutaneous or fascial tissues, there may also be a characteristic round facies, defective dentition, mental retardation, calcification of basal ganglia, calcinosis circumscripta-like lesions,²¹⁹ cataracts, and characteristic short, thick-set fingers with stubby hands and feet attributable to early closure of the metacarpal and metatarsal epiphyses.^{213,214}

A case reported as progressive extensive osteoma cutis associated with dysmorphic features may be a new syndrome.²²⁰

Progressive osseous heteroplasia

Progressive osseous heteroplasia (OMIM 166350) is an exceedingly rare autosomal dominant condition first described by Kaplan in

Figure 14.4 Calciphylaxis. (A) Calcium deposits in the wall of a subcutaneous vessel. (H&E) (B) Involvement of the subcutaneous fat. (H&E) (C) The small calcium deposits can be seen in vessels and thin collagenous septa. (von Kossa)

1996.^{221,222} It presents as dermal ossification in infancy, followed by progressive ossification of skin, subcutaneous fat, and deep connective tissue.²²²⁻²²⁴ Complications include skin ulceration and discharge of bony material, recurrent infections, joint ankylosis, and growth retardation.

Paternally inherited inactivating mutations of the *GNAS1* gene on chromosome 20q13 have been implicated in the pathogenesis. Various other mutations in the gene have since been described.²²² Phenotypic expression of the same gene mutation is variable.

Congenital plaque (plate)-like osteomatosis

Congenital plaque (plate)-like osteomatosis consists of the slow development of a large mass of bone in the lower dermis or subcutaneous tissues.^{195,225,226} It is present at birth or soon afterwards. It appears to be a variant of progressive osseous heteroplasia (discussed previously) with the same defect in the *GNAS1* gene. It has been reported to involve the thigh,²²⁷ scalp,²²⁸⁻²³⁰ back,²³¹ and calf.²³² Two cases reported as 'limited dermal ossification', although much more extensive in distribution than the typical plaque-like lesion just described, are best included in this category.^{233,234}

Fibrodysplasia ossificans progressiva

The extremely rare, autosomal dominant condition of fibrodysplasia ossificans progressiva (OMIM 135100) is manifested by hallux valgus, shortening of the great toes and thumbs, and ossification in muscles and connective tissue.²³⁵ Dermal ossification may precede or accompany these changes. Chondral elements may also be present. The muscles of the shoulder and axial skeleton are commonly involved.

It is caused by a mutation in the *ACVRI* gene on chromosome 2q23.²³⁶ As a consequence of this defect, there is overexpression of bone morphogenetic protein-4 (BMP-4), which may be responsible for the deposition of bone. The noggin (*NOG*) gene may be responsible in rare cases, although some published reports implicating this gene were not able to be confirmed in other laboratories.

Secondary ossification

This group accounts for the great majority of cases of cutaneous ossification.^{189,195,225} Bone may be found in nevi, particularly on the face (osteonevus of Nanta); in basal cell carcinomas; in up to 20% of pilomatrixomas; and less commonly in trichoepitheliomas, hemangiomas, pyogenic granulomas,²³⁷ schwannomas, lipomas, chondroid syringomas, ossifying plexiform tumor,²³⁸ organoid nevi,²³⁹ epidermal and dermoid cysts, dermatofibromas, desmoplastic melanomas,²⁴⁰ and some cutaneous metastases.²⁴¹ This subcategory of secondary ossification (ossification in tumors) accounted for 56 of the 74 cases of cutaneous ossification in one large series.¹⁸⁹ Ossification may also develop in sites of infection, trauma, and scarring, such as acne scars,^{242,243} injection sites, hematomas, and surgical scars. Myositis ossificans and the related fibro-osseous pseudotumor of the digits²⁴⁴ can also be included. Abdominal wounds are particularly involved, and it seems that injury to the xiphoid process or pubis may liberate bone-forming cells into the wound with subsequent ossification that appears within the first 6 months after surgery.²⁴⁵ Other circumstances include chronic venous insufficiency of the legs,²⁴⁶ scrotal calcinosis,¹⁹⁵ auricular calcinosis,⁶³ scleroderma, morphea,²⁴⁷⁻²⁴⁹ dermatomyositis, and, rarely, gouty tophi. Secondary ossification has also been reported in neurological diseases associated with paralysis²⁵⁰ and in a plaque of alopecia in a patient with polyostotic fibrous dysplasia.²⁵¹ Bone formation occurs in hypertrophic osteoarthropathy, which may be secondary to pulmonary disease (finger clubbing) or occur as a primary disease resulting from mutations in the *HPGD* gene that encodes 15-hydroxyprostaglandin dehydrogenase.²⁵²

Figure 14.5 Osteoma cutis. The spicules of bone are undergoing transepidermal elimination. Surface crusting is present. (H&E)

Histopathology

Cutaneous bone usually develops by membranous (mesenchymal) ossification without the presence of a cartilage precursor. There are small spicules or large masses of bone in the deep dermis and/or subcutaneous tissue (**Fig. 14.5**). Haversian systems and cement lines are usually present. Occasionally, there is active osteoblastic activity, particularly in Albright's hereditary osteodystrophy, but this is unusual in the primary solitary lesion and secondary forms associated with acne scars. Biopsies of progressive osseous heteroplasia show extensive ossification in the dermis, subcutis, and/or underlying muscle.²⁵³ Osteoclasts are also uncommon. There is often a stromal component of fat, but occasionally hemopoietic cells are also present. In the congenital plaque-like osteomatosis, bone may extend around the dermal appendages (**Fig. 14.6**).²²⁵ Pigmentation of the bone has been reported in acne patients receiving tetracycline or minocycline: clinically, these nodules may have a bluish color.^{254–256} The crystalline component of the bone is hydroxyapatite, as in skeletal bone.

Differential diagnosis

Subungual exostosis and subungual osteochondroma may be variants of the same lesion, but there are some clinical and microscopic differences between the two, leading some authors to conclude that they are distinctive. In contrast to subungual osteochondromas, exostoses arise in females more often than in males, are often preceded by trauma or infection (i.e., representing 'pseudotumors'), and develop in the distal tuft of the phalanx rather than the epiphyseal line. Exostoses have a cap of fibrocartilage rather than hyaline cartilage, and the distal phalangeal tuft develops via enchondral ossification. Microscopically, the fibrocartilaginous cap is hypercellular, showing plump nuclei and multinucleation; this is in contrast to the cartilaginous cap of osteochondroma, in which chondrocytes are arranged in a manner resembling a normal growing epiphysis.

CARTILAGINOUS LESIONS OF THE SKIN

The term 'cartilaginous lesions of the skin' encompasses several different entities, which have in common the presence of cartilage of variable maturity. Some of these entities have been discussed in other sections. The following classification has been suggested by Hsueh and Santa Cruz.²⁵⁷

Figure 14.6 (A) Plaque-like osteoma cutis of the scalp. (B) Bone extends around the eccrine glands. (H&E)

Chondromas

True cutaneous chondromas,^{258,259} without bony connection, are an exceedingly rare dermal tumor (see p. 1038).

Hamartomas containing cartilage

The hamartomas containing cartilage include accessory tragi, the closely related Meckel's cartilage (cartilaginous rests in the neck, 'wattles'^{260–263}), bronchogenic cysts, and dermoid cysts. The lesions reported as elastic cartilage choristomas of the neck²⁶⁴ were midline and suprasternal and therefore different from the usual laterally placed branchially derived remnants.

Soft tissue tumors with cartilaginous differentiation

These extraskeletal tumors arise most frequently in the soft tissues of the extremities, especially the fingers.²⁶⁵ They may have varying degrees of cytological atypia in the chondrocytes, but despite this they invariably pursue a benign course.

Skeletal tumors with cartilaginous differentiation

This group includes osteochondromas, synovial chondromatosis, and subungual exostoses (see p. 1038).

Miscellaneous lesions

The eccrine tumor, chondroid syringoma, may have prominent cartilaginous differentiation that may at first glance obscure its sweat gland origin. Cartilage may develop in degenerated nuchal ligaments producing the **nuchal fibrocartilaginous pseudotumor**.^{266,267}

The case described as 'cartilaginous papule of the ear' defies classification.²⁶⁸ It may represent a reactive hyperplasia of auricular cartilage.

HYALINE DEPOSITS

Hyaline deposits may be seen in the dermis in several 'metabolic' disorders, including amyloidosis, erythropoietic protoporphyria and lipoid proteinosis, and Waldenström's macroglobulinemia. In gouty tophi, the deposits are of a crystalline nature, but when these are dissolved in an aqueous fixative the residual stromal tissue appears hyaline. Other causes of hyaline deposits are colloid milium and massive cutaneous hyalinosis; they may also occur following certain corticosteroid injections. Cytooid bodies are a heterogeneous group of hyaline deposits that are commonly overlooked in routine sections.

An unclassifiable deposit, of hyaline type, has been reported in a patient with IgG paraproteinemia and lesions resembling cutis laxa.²⁶⁹ Eosinophilic homogeneous material was present in the dermis. The material had a tubular pattern on electron microscopy.²⁶⁹ Eosinophilic deposits have been reported in the base of a cutaneous ulcer and forming follicular plugs in two patients with multiple myeloma.²⁷⁰ The deposits were monoclonal and identical to those found in the serum.²⁷⁰

GOUT

Although the prevalence of gout in the community is relatively constant, the proportion of gouty patients with cutaneous manifestations – tophi – shows a continuing decline.^{3,271} This undoubtedly results from improved clinical management of these patients, particularly the use of allopurinol, a xanthine oxidase inhibitor that blocks uric acid

production. Tophi, which are end-stage manifestations of primary gout, are deposits of monosodium urate crystals within and around joints, overlying the olecranon and prepatellar bursae and in the helix of the ears.^{272,273} Sometimes chalky white material is extruded from tophi. Smaller nodular deposits have been described on the fingers and toes, and milia-like papules representing intradermal tophi have been found in locations other than the joints.²⁷⁴ There are reports of leg ulcers or a panniculitis with urate deposition as the presenting manifestations of gout.^{275–277} Tophi have been reported in a patient following the use of acitretin, an oral retinoid, in the treatment of erythrodermic psoriasis.²⁷⁸

Histopathology

Tophi are dermal and subcutaneous deposits of urate crystals.²⁷⁹ If material is fixed in alcohol, they appear as well-demarcated deposits of closely arranged, brown, needle-shaped crystals (Fig. 14.7). The crystals are doubly refractile under polarized light (Fig. 14.8). In

Figure 14.7 Gouty tophus. There are brown, needle-shaped crystals forming large deposits in the dermis and subcutis. The biopsy was fixed in alcohol. (H&E)

Figure 14.8 Gout; urate crystals under polarized light. Urate crystals fixed in alcohol are weakly negatively birefringent when examined under polarized light using a red filter. They are yellow when oriented parallel to the direction of the slow wave and blue when oriented at 90 degrees.

Figure 14.9 Gouty tophus. The urate crystals have been dissolved in this formalin-fixed biopsy, leaving a pale hyaline area surrounded by macrophages and foreign body giant cells. (H&E)

formalin-fixed material, the crystals will usually have dissolved, and there are characteristic, amorphous pink areas corresponding to the sites of crystal deposition (Fig. 14.9). Surrounding the deposits is a granulomatous reaction with macrophages and many foreign body giant cells.²⁸⁰ There is usually only a sparse chronic inflammatory cell infiltrate. Often, there is some fibrosis as well, and in old lesions calcification and even ossification may occasionally develop. Transepidermal elimination of crystals is rarely seen.²⁸¹

It has been suggested that the primary event in the formation of a tophus is the accumulation of macrophages in an acinar arrangement followed by the centripetal transport of urate by the macrophages from the interstitial fluid to the central zone.²⁸⁰ This expands progressively as more urate crystals are deposited. The corona of macrophages commonly disappears, and adjacent deposits may fuse.²⁸⁰

Differential diagnosis

The distinctive features of urate crystals, when present in alcohol-fixed tissue sections, are usually diagnostic. The distinction from oxalate crystals is discussed later. Pseudogout, due to calcium pyrophosphate dihydrate deposition, is rarely encountered in skin and does not produce tophus-like lesions. However, those crystals show positive birefringence with polarization microscopy. In contrast to urates, when examined with a red filter, the calcium pyrophosphate crystals are blue when the long axis of the crystals is parallel to the axis of the slow wave and yellow when their long axis is oriented at 90 degrees. When tissue sections have been fixed in formalin, the characteristic crystalline structure of the urate crystals is generally lost, and the remaining material has an amorphous gray appearance. However, the color of this material is quite different from that of the contents of epithelial cysts, which might also be considered in the differential diagnosis. In difficult cases, urates could be shown not to stain as calcium or to be positive for keratin. The authors' experience has been that large urate deposits may not fix completely in formalin solutions; in such cases, the central portion of the aggregates may still exhibit the characteristic crystalline structure, staining, and birefringent properties. Several cases of panniculitis associated with fungal infection, notably mucormycosis and aspergillosis, have also displayed necrotic adipocytes, resembling the ghost cells of pancreatic panniculitis, and refractile, radially oriented crystals, resembling urate crystals in tissues fixed in alcohol. It has been speculated that the latter change could be related to the proteases produced by fungi, which can degrade cellular and extracellular matrix

material, the products of which may then be metabolized to uric acid.^{282,283}

AMYLOIDOSIS

Amyloidosis refers to the extracellular deposition of eosinophilic hyaline material of autologous origin that has characteristic staining properties and a fibrillar ultrastructure.²⁸⁴⁻²⁸⁸

The origin of amyloid is diverse: 16 different fibril proteins have been described so far.²⁸⁹ Many of these are rare or have no relevance to the skin. Six amyloid proteins are of interest in cutaneous pathology: AA, ATTR, AL, AK, A β_2 M, and AK.²⁸⁹⁻²⁹¹ Mixed amyloid deposits, containing two or more of these proteins, are uncommon.^{292,293}

- AA (amyloid A protein) is associated with chronic inflammatory diseases, corresponding to secondary systemic amyloidosis of the traditional classification
- ATTR (amyloid transthyretin protein) is found in cases of familial amyloidosis.²⁹⁴ It appears to be the same as FAP (familial amyloid polyneuropathy, type 1)
- AL and AK are usually grouped together as AL (amyloid light-chain protein). These proteins are found in relation to myeloproliferative diseases, particularly multiple myeloma, or in cases with no known associated disease (idiopathic). AL is found much more commonly than AK. It is the type of amyloid usually found in nodular cutaneous amyloidosis. This type of amyloid (AL) is the most difficult type to confirm immunohistochemically because staining for the two light chains λ or κ may be spotty and uneven.²⁹⁵
- A β_2 M (amyloid β_2 -microglobulin protein) is found in amyloid deposits associated with long-term hemodialysis.^{289,296} It deposits mainly in the osteoarticular system,²⁹⁷ but subcutaneous deposits have been reported.²⁹⁶ Improvements in hemodialysis have led to the disappearance of this type of amyloid.²⁹⁵
- AK (amyloid keratin protein) is found in localized cutaneous amyloidosis, both lichen amyloidosis and macular amyloidosis. This protein is discussed further later.

In addition to the specific fibrillar component, amyloid deposits have been shown to contain several associated and contaminating proteins, such as amyloid P, apolipoprotein E, and glycosaminoglycans.^{289,298} Immunoglobulins may be nonspecifically trapped within the fibrillar meshwork. Amyloid P, which for a long time was used as a marker for amyloid, is a nonfibrillar glycoprotein that binds to all types of amyloid fibrils.

In primary cutaneous amyloidosis, the amyloid is of keratinocyte origin, but how the keratin intermediate filaments transform into amyloid (AK) is speculative. Apoptosis of keratinocytes has been described, but this may simply be the method of cell death in basal keratinocytes that have accumulated an abnormal protein.²⁹⁹ Another theory is that macrophages in the dermis 'process' the filament-rich colloid bodies, converting them into mature amyloid and in the process adopt a β -pleated sheet pattern (as opposed to the usual α pattern of keratin). Active secretion of amyloid by basal keratinocytes is a less favored theory.^{300,301} AK stains with general keratin antibodies, such as EKH4 and AE1.²⁹⁹ Several subclasses of keratin are found, in particular CK5, which is a constituent of normal basal keratinocytes.²⁹¹ However, the presence of CK7, CK17, and CK19, not found in the interfollicular epidermis, suggests an appendageal contribution to the amyloid deposits.²⁹¹ Suggested etiological factors in the formation of this type of amyloid include prolonged friction, pruritus, genetic predisposition, Epstein-Barr virus, and environmental factors.

The skin may be involved in the course of systemic (generalized) amyloidosis, but more commonly it is the only organ in the body to be involved – localized cutaneous (skin-limited) amyloidosis. Within

each of these two major categories, several distinct clinical variants are found, as outlined in the traditional classification that follows:

- **Systemic amyloidosis**
 - Primary and myeloma associated
 - Secondary
 - Heredofamilial
 - Amyloid elastosis
- **Localized cutaneous amyloidosis**
 - Lichen, macular and biphasic
 - Nodular
 - Poikilodermatous
 - Anosacral
 - Familial cutaneous
 - Secondary localized.

The histochemical, immunofluorescence, and ultrastructural properties of the various cutaneous amyloidoses are discussed before the description of the individual clinical variants.

Histochemical properties

Amyloid stains pink with H&E and metachromatically with crystal violet and methyl violet.³⁰² It stains selectively with Congo red; in addition, amyloid stained by Congo red gives an apple-green birefringence when viewed in polarized light (Fig. 14.10). Amyloid gives a bright yellow-green fluorescence with thioflavine T.³⁰³ We have found crystal violet to be more reliable than Congo red in sun-damaged skin, which sometimes gives false-positive staining with Congo red; false negatives also occur. The cotton dye pagoda red No. 9 (Dylon®), used as a variant of the Congo red method, is said to be more specific for amyloid than Congo red because it does not stain the material in paraffin sections of lipoid proteinosis, colloid milium, or solar elastosis.^{304–306} Congo red staining of the deposits in secondary systemic amyloidosis can be prevented by prior treatment of the sections with potassium permanganate.^{307,308} In some cases of primary systemic amyloidosis, the amyloid has relatively little affinity for Congo red.³⁰⁹ Early cases of localized cutaneous amyloidosis can also be negative using the Congo red method. The author has seen several cases of lichen amyloidosis missed because only a Congo red stain was performed.

Immunoperoxidase methods using monoclonal antisera can also be used to demonstrate amyloid P component (a nonfibrillar protein derived from a glycoprotein found in the blood of all normal persons) in all cutaneous deposits.^{310–313} As previously mentioned, the amyloid in lichen amyloidosis and macular amyloidosis, as well as in secondary

localized cutaneous amyloidosis, stains with the monoclonal antibody EKH4, which recognizes 50-kDa neutral and acidic keratin.³⁰⁴ It also stains with the keratin antibody AE1. The antikeratin antibody EAB-903, which recognizes 57- and 66-kDa keratin peptides, reacts with the amyloid deposits in both lichen amyloidosis and macular amyloidosis but not with the amyloid in systemic amyloidosis.³¹⁴ Other keratin monoclonals have given mixed results.^{314–317} Antisera are also available commercially against AA, AL, both anti- λ and anti- κ , islet amyloid polypeptide (IAPP), and A β ₂M. Amyloid deposits can be misclassified if the antibody panel is incomplete.³¹⁸

Immunofluorescence

Immunoglobulins, particularly IgM, and C3 complement are found in cutaneous amyloid deposits.^{319,320} Most of the studies have been confined to the localized cutaneous forms. Amyloid is thought to act like a filamentous sponge with nonspecific trapping of the immunoglobulins and complement.³²¹

Ultrastructure³⁰⁵

Amyloid is composed of straight, nonbranching filaments, 6–10 nm in diameter, of indefinite length and in random array (Fig. 14.11). A close association with elastic fibers is sometimes observed.^{322–324} Intracellular amyloid has been noted in dermal fibroblasts^{325,326} and in keratinocytes in lichen amyloidosis.³²⁵

The ultrastructural studies of Hashimoto and colleagues^{327,328} and other groups^{329–331} have shown that the basal epidermal cells are involved in the histogenesis of the amyloid in lichen amyloidosis and macular amyloidosis. Basal keratinocytes overlying dermal amyloid show degenerative changes with the accumulation of modified tonofilaments (thicker but less electron-dense than normal) in the cytoplasm.³³²

Primary systemic amyloidosis

Primary systemic amyloidosis (AL) is a rare disorder with an incidence of approximately 8 per 1 million persons per year.³³³ However, cutaneous involvement is common in this form of amyloidosis and in the closely related myeloma-associated amyloidosis, with lesions in approximately one-third of patients.^{284,334,335} There are nonpruritic, waxy papules on the scalp, face, and neck and sometimes the genitalia.^{308,336–338} There is a predilection for the periorbital areas. Plaque-like

Figure 14.10 Amyloid; Congo red staining under polarized light. The apple green birefringence can be seen in this example.

Figure 14.11 Lichen amyloidosis. There are intracellular deposits and some dense tonofilament bundles in basal keratinocytes. The deposits appear to represent the earliest stages of amyloid formation. (×45,000)

lesions may develop on the hands and flexural areas.³³⁹ Hemorrhage into the lesions is quite common.^{337,340-342} Rare presentations include alopecia,^{343,344} occlusion of the external auditory canals,^{345,346} chronic paronychia,³³⁹ nail dystrophy,^{347,348} digital nodules,³⁴⁹ bullous lesions,^{334,350-354} indurated cord-like lesions resulting from thick vascular deposits,³⁵⁵ condyloma-like lesions in the perianal region,³⁵⁶ muscle pseudohypertrophy,³⁵⁷ and elastolytic lesions (acquired cutis laxa).³⁵⁸⁻³⁶⁰ As mentioned previously, the fibrillar protein is derived from light chains of immunoglobulin (AL), either λ or κ . The coexistence of β_2 -microglobulin has been reported.²⁹³

Lenalidomide, an analogue of thalidomide, has been used in the treatment of amyloidosis associated with multiple myeloma.³⁶¹ There is a high incidence of cutaneous adverse reactions to this therapy. Promising results have been obtained with the proteasome inhibitor bortezomib.³⁶² The median survival of patients with systemic amyloidosis is approximately 13 months from diagnosis.³³³

Histopathology

Papular lesions result from deposits of amyloid in the papillary dermis; in plaques, there is a more diffuse dermal infiltration, sometimes with extension into the subcutis (Fig. 14.12).³⁶³ In this latter site, amyloid deposits around individual fat cells to form 'amyloid rings' (Fig. 14.13). Dermal blood vessels are usually involved in hemorrhagic lesions (Fig. 14.14), and pilosebaceous units are involved in areas of alopecia.^{337,363}

The rare bullous lesions are caused by intradermal cleavage within the amyloid deposits.^{334,364} There is often clefting about and within the amyloid in the larger papular lesions. If the deposits are large, there is often attenuation of the overlying epidermis.³⁶³ There are no pigmented cells, and inflammatory cells are scarce.³⁶⁴

Clinically normal skin will show deposits of amyloid in the dermis, usually in the walls of blood vessels, in more than 50% of biopsies in cases of primary systemic amyloidosis.³⁶⁵ One study found cutaneous amyloid deposits in 97% of cases of systemic amyloidosis, making skin biopsy a preferred method of diagnosis of systemic amyloidosis.²⁹⁰ Abdominal fat aspiration is another procedure,³⁶⁶ but a large series from the Mayo Clinic found a low yield by this technique.³⁶⁷

Secondary systemic amyloidosis

Clinical involvement of the skin is rare in cases of secondary systemic amyloidosis.^{284,363} Uncommonly, this form of amyloidosis is the result of an underlying chronic skin disease such as lepromatous leprosy, mycosis fungoides, hidradenitis suppurativa, arthropathic psoriasis,^{307,368,369} Schnitzler's syndrome,³⁷⁰ or dystrophic epidermolysis bullosa.³⁷¹ Although no cutaneous involvement was recorded, renal amyloidosis has been reported in a patient with concurrent familial Mediterranean fever and pseudoxanthoma elasticum.³⁷² Both diseases involve gene mutations in the 16p13 region. Secondary amyloidosis may occur following hemodialysis; in these circumstances, the protein fibril deposited is β_2 -microglobulin.^{297,373,374} In other circumstances, the fibrillar component is amyloid A protein (AA). It has been suggested that the presence of AL amyloidosis may enhance the development of AA amyloidosis.³⁷⁵

Histopathology

Amyloid has been found in several sites in the clinically normal skin of some patients with secondary amyloidosis, including the papillary dermis, the subcutis, the walls of blood vessels, and around eccrine sweat glands.³⁶³⁻³⁶⁵

Heredofamilial amyloidosis

There are skin manifestations in certain of the heredofamilial amyloidoses.³⁷⁶ These include trophic changes and amyloid deposits in the

Figure 14.12 Primary amyloidosis. (A) The hyaline deposits in the dermis show some artifactual separation. (H&E) (B) Another case with deposition accentuated in the upper dermis. (H&E, with crystal violet inset)

Figure 14.14 Primary amyloidosis. (A) There is considerable hemorrhage between the hyaline deposits. (B) A small artery in the subcutis has thickening of its wall due to amyloid deposition. (H&E)

arrector pili muscles in (heredo) familial amyloid polyneuropathy^{285,305,377} and urticaria in other forms, such as the Muckle-Wells syndrome (urticaria, amyloidosis, and deafness).^{378,379} The major pathological hallmark of FAP is the formation of transthyretin-derived amyloid deposits in several organs.²⁹⁴ The disease (OMIM 176300) has an autosomal dominant manner of inheritance. The gene map locus is 18q11.2–q12.1. It is endemic in the northern area of Portugal, but it has also been reported in patients of non-Portuguese descent.³⁸⁰ There are also endemic regions in Sweden and Japan.³⁸¹ The Finnish type of amyloidosis is mentioned later.

Amyloid elastosis

Amyloid elastosis is an exceedingly rare form of amyloidosis with cutaneous lesions and progressive systemic disease.^{382,383} The elastic fibers in the skin and serosae are coated with the amyloid material;³⁸² the amyloid is localized to the microfibrils of the elastic fibers.³⁸⁴ Why amyloid is preferentially deposited on elastic fibers, resulting in clinically evident lesions, is unknown. It is a variant of systemic AL amyloidosis.³⁸⁵

Amyloid is also deposited around elastic fibers in the skin, producing cutis laxa in hereditary gelsolin amyloidosis (familial amyloidosis of the Finnish type; OMIM 105120) caused by a mutation in the *gelsolin* gene on chromosome 9q34.^{386,387}

Histopathology

A recent report described a woman with multiple myeloma who had whitish to flesh-colored papules in cervical, flexural, abdominal, and lumbar areas. Skin biopsy showed basophilic elastic fibers, some of which were fragmented, with numerous small protrusions creating a 'fishbone' appearance with orcein staining. Ultrastructural studies showed microfibrils suggestive of amyloid coating the elastic fibers.³⁸⁸ In a case of hereditary gelsolin amyloidosis, elastic fibers in the lower reticular dermis were reduced in number, fragmented, and aggregated. Basement membranes of epidermis, sweat glands, and hair follicles displayed red-green fluorescence after Congo red staining, and these same structures stained positively with an anti-gelsolin amyloid antibody.³⁸⁹

Lichen, macular, and biphasic amyloidoses

Lichen amyloidosis and macular amyloidosis are clinical variants of the same process.^{305,390,391} Patients with features of both variants, or transformation from one to the other (biphasic form), are well documented.^{392–395} There is no visceral involvement in lichen amyloidosis or macular amyloidosis.³⁹⁶ An association with multiple endocrine neoplasia syndrome 2A (MEN 2A; OMIM 171400) has been reported.^{397,398} A Brazilian family with localized cutaneous amyloidosis (OMIM 105250) due to a mutation in the oncostatin M receptor- β (OSMR) gene has been reported.³⁹⁹ Other reported associations are possibly coincidental, although chronic pruritus could be implicated in two such associations.^{400–403} The fibrillar component is derived from keratinocytes and designated AK (amyloid keratin). All of the cyto-keratins detected in the deposits are of basic type (type II). CK5 is strongly expressed.⁴⁰⁴

Lichen amyloidosis presents as small, discrete, often pruritic, waxy papules with a predilection for the extensor surfaces of the lower extremities.^{396,405} Rare clinical presentations have included similar distribution in identical twins,⁴⁰⁶ a thermosensitive distribution with sparing of areas with a higher temperature,⁴⁰⁷ and involvement of the glans penis.^{408,409} Lichen amyloidosis is not uncommon in Southeast Asia and some South American countries.^{396,410} It has been associated with chronic Epstein-Barr virus infection,^{411,412} Kimura's disease,⁴¹³ and angiolymphoid hyperplasia with eosinophilia.⁴¹⁴ Others

believe it is a consequence of chronic scratching.^{415,416} This may be the explanation for its rare occurrence in HIV-associated papular pruritus⁴¹⁷ and in refractory atopic dermatitis.⁴¹⁸ However, a generalized case of lichen amyloidosis, without pruritus, has been reported.⁴¹⁹ Nerve fibers are reduced at the dermoepidermal junction but not in the papillary dermis, leading to the suggestion that the pruritus may result from hypersensitivity of the nerve fibers that remain following the unexplained loss of nerves at the dermoepidermal junction.⁴²⁰

Dermabrasion, combined bath PUVA photochemotherapy and oral acitretin, acitretin alone, hydrocolloid dressings, and the pulsed dye laser have been used in the treatment of lichen amyloidosis.^{421–425}

Macular amyloidosis is relatively common in Asia and the Middle East.⁴²⁶ It occurs as poorly defined hyperpigmented and rippled patches on the trunk.^{331,427} Rarely, there is widespread pigmentation.^{428–430} Pigmentation resembling incontinentia pigmenti has been reported. It was associated with subepidermal blister formation.⁴³¹ There is a predilection for the interscapular region of adult females.⁴³² Lesions are often pruritic. Macular amyloidosis has been reported in Japanese individuals following prolonged rubbing of the skin with nylon brushes and towels.^{304,433,434} Other types of friction have sometimes been implicated.^{435,436} Unusual presentations include involvement of the thighs,⁴³⁷ knees,⁴³⁸ or elbows.⁴³⁹ The Q-switched Nd:YAG laser has been used to reduce the pigmentation in patches of macular amyloidosis.⁴⁴⁰

Histopathology

Both lichen amyloidosis and macular amyloidosis are characterized by small globular deposits of amyloid in the papillary dermis (**Fig. 14.15**).³²⁰ Sometimes a thin band of compressed collagen separates these deposits from the overlying epidermis;³⁹⁶ other times, the deposits are in contact with the basal cells and sometimes interspersed between them. More extensive deposits are sometimes seen (see **Fig. 14.15B**). Transepidermal elimination of the amyloid sometimes occurs.⁴⁴¹ Subepidermal clefting above the deposits rarely occurs.⁴⁴² Pigmented cells are often seen within the dermal deposits. The presence of these cells is an important clue to the diagnosis of primary cutaneous amyloidosis on H&E-stained sections.

In lichen amyloidosis (**Fig. 14.16**), the overlying epidermis shows hyperkeratosis and acanthosis, with the changes sometimes resembling those of lichen simplex chronicus (see p. 96).⁴⁴³

In both types of amyloidosis, occasional apoptotic bodies are present within the epidermis.⁴⁴⁴ Basal vacuolar change also occurs.

As previously mentioned, the author routinely uses the crystal violet stain to confirm the amyloid deposits. It is superior to both alkaline and Highman's Congo red stains. The detection of cytokeratins (using an LP34 clone that detects CK5, -6, and -18) is the new gold standard.⁴⁴⁵

Shiny white streaks can be seen in the lesions of lichen amyloidosis using polarizing dermoscopy.⁴⁴⁶

Differential diagnosis

Amyloid deposits have a resemblance to the colloid material seen in adult and juvenile colloid milium. Colloid should not be positive for Congo red, although this has been reported, and adult colloid milium has a close relationship to solar elastosis; a link between amyloid deposition and elastic tissue has only rarely been reported. Juvenile colloid milium is derived from and stains for keratins; this is also true of macular and lichenoid forms of amyloidosis, but deposits in the latter also stain positively with crystal violet, Congo red (although not invariably), and for amyloid P component. A variant histochemical stain, the van Gieson stain (without the component for elastic fibers), can also be helpful in that amyloid stains pink and colloid stains yellow. If needed, electron microscopy can be useful in distinguishing between the two deposits, in that filaments of juvenile colloid milium are wavy

Figure 14.15 Macular amyloidosis. (A) Hyaline material, barely distinguishable from collagen, is present in the papillary dermis. The diagnosis can be easily missed. (H&E) (B) The deposits are more extensive than usual. (Pagoda red)

Figure 14.16 Lichen amyloidosis. (A) Small, hyaline deposits of amyloid are situated in the papillary dermis. There is overlying epidermal hyperplasia. (H&E) (B) The size of the deposits can be better appreciated on the special stain for amyloid. (Congo red) (C) The preferable stain for amyloid keratin is the crystal violet stain, shown here. (Crystal violet)

Figure 14.17 Auricular amyloidosis. This condition was formerly known as 'collagenous papules of the ear'. (H&E)

or whorled with a diameter of 8–10 nm and those of adult colloid milium are smaller in diameter and show a close relationship with degenerated elastic fibers. There may also be some resemblance to amyloid in two other conditions characterized by the dermal deposition of amorphous, eosinophilic material: erythropoietic protoporphyria and the rare autosomal recessive disorder lipid proteinosis. In both of these conditions, there is ultrastructural evidence for reduplication of basal lamina material (although lipid proteinosis may show disruption as well as reduplication of epidermal basal lamina), and in lipid proteinosis, there are also dermal deposits of granular material interspersed with fine collagen fibrils. These features are quite different from those of amyloid. Staining shows neutral mucopolysaccharide, variable amounts of lipid, and (by immunohistochemistry) collagen, including type IV collagen; stains for amyloid are negative, although occasional reports of weak Congo red positivity have been published.

Auricular amyloidosis

Auricular amyloidosis (amyloidosis of the auricular concha) has also been reported in the past as 'collagenous papules of the ear'.^{447–449} It presents with papules or plaques localized to the ear.^{450,451} It may be a variant of lichen amyloidosis (Fig. 14.17). The deposits are localized to widened dermal papillae.⁴⁵⁰ It is not as rare as the paucity of reports would suggest. One additional case was reported in 2013.⁴⁵²

Nodular amyloidosis

Nodular amyloidosis is an uncommon form of cutaneous amyloidosis that is manifested by solitary⁴⁵³ or multiple waxy nodules, 0.5–7 cm in diameter, on the lower extremities,⁴⁵⁴ face,^{455–460} neck,⁴⁶¹ scalp, or genital region.^{462–467} An example with corymbiform features (i.e., in a flower-like cluster) has been described.⁴⁶⁸ In at least 15% of cases, the patient will subsequently develop systemic amyloidosis.^{443,464,469} None of the 16 patients with nodular amyloidosis reported from the Mayo Clinic had progressed to systemic amyloidosis at the time of the study.⁴⁷⁰ In another study, the rate of progression was 7%.⁴⁷¹ Associations with CREST syndrome⁴⁷² and Sjögren's syndrome^{473,474} have been reported; the amyloid deposits in these cases were light chain-derived. A light-chain origin of the AL has been proved in many cases.^{462,466,475,476} Trauma was implicated in one case.⁴⁷⁷ Amyloid oligomers have been detected in primary cutaneous nodular amyloidosis, formed mainly of

λ light-chain immunoglobulins with lesser amounts of κ light-chain oligomers; immunoglobulin oligomers are apparently toxic to human keratinocytes.⁴⁷⁸

Nodular deposits of amyloid, derived mostly from β_2 -microglobulin, are a rare finding in the skin of patients with chronic renal failure on long-term hemodialysis.^{296,297} 'Amyloidoma' refers to a rare tumor mass of amyloid that may be found in the subcutis.⁴⁷⁹⁻⁴⁸² It may be composed of AA, AL, or IAPP amyloid.⁴⁷⁹ Injection site nodular amyloid deposits have also been reported. In one case, the nodule was the site of repeated insulin injections in a diabetic patient.⁴⁸³

Histopathology

There are large masses of amyloid in the dermis and subcutis, with accentuated deposition around deep vascular channels and adnexal structures.³³⁷ Plasma cells, some with large Russell bodies, are usually quite prominent at the margins and within the amyloid islands.^{364,464,484} Monoclonality of these cells has been confirmed.^{470,485,486} The deposits do not stain with antikeratin antibodies.²⁹¹ They may stain for A λ , A κ , or A β_2 M (discussed previously). Foreign body giant cells and focal calcification are sometimes present.^{464,487} The amyloid may be deposited in relation to the elastica.^{322,488} In the case of nodular amyloid due to repeated insulin injections, in addition to Congo red-positive amyloid material, strong anti-human insulin antibody staining was found throughout the nodule; stains for AA amyloid, apolipoprotein A-I, fibrinogen, lysozyme, κ and λ light chains, and transthyretin were negative.⁴⁸³

Poikilodermatous amyloidosis

Poikilodermatous lesions are rare.⁴⁸⁹ A distinct subset of patients have short stature, early onset, light sensitivity, and sometimes palmoplantar keratoderma – the poikilodermatous cutaneous amyloidosis syndrome.⁴⁸⁹ This is not to be confused with the rare case of poikilodermatous mycosis fungoides coexisting with localized cutaneous, keratin-derived amyloid deposition.⁴⁹⁰

Included in this category are the cases reported as **amyloidosis cutis dyschromica**.^{491,492} It is characterized by reticulate hyperpigmentation with hypopigmented spots over much of the body. One case was associated with hypopigmented and hyperpigmented papules.⁴⁹³ It is assumed to be a familial disorder.⁴⁹⁴ In a series of 10 cases from the Zhejiang Province of China, 5 cases were from one family and the other 5 were sporadic.⁴⁹⁵

Histopathology

There is amyloid in the dermal papillae and around dermal blood vessels, resembling the pattern of primary systemic amyloidosis. In recent reports of amyloidosis cutis dyschromica, deposits in dermal papillae are emphasized; these are variably crystal violet and Congo red positive, and those tested have been positive for cytokeratins.^{493,495-498} The example with papular lesions demonstrated amyloid deposits both in these and in the macular lesions.⁴⁹³

Anosacral amyloidosis

Anosacral amyloidosis is a rare form of primary cutaneous amyloidosis that has been reported in Chinese persons.⁴⁹⁹ It presents as a light brown lichenified plaque of the perianal region extending onto the lower sacrum. The amyloid is of keratinous origin (AK).

Histopathology

The amyloid deposits are situated in the papillary dermis. There is some overlying epidermal hyperkeratosis, acanthosis, and melanin incontinence.⁴⁹⁹

Differential diagnosis

Anosacral amyloidosis should be distinguished from a somewhat similar-appearing clinical condition, **senile gluteal dermatosis**, which appears to be common in Japan. A clinical distinction is that patients with anosacral amyloidosis often have lesions of macular or lichenoid amyloidosis at other body sites, whereas senile gluteal dermatosis is concentrated over the gluteal cleft and both sides of the buttocks, forming a tri-corner arrangement. Microscopically, senile gluteal dermatosis features hyperkeratosis, acanthosis, and vasodilatation; lacks lichenoid changes or significant pigment incontinence; and lacks amyloid deposits.⁵⁰⁰

Familial primary cutaneous amyloidosis

Familial primary cutaneous amyloidosis is an extremely rare, autosomal dominant genodermatosis with keratotic papules and/or swirled hyper- and hypopigmentation⁵⁰¹ on the extremities and sometimes the trunk.^{337,502,503} The clinical features may resemble lichen amyloidosis.⁵⁰⁴ The deposits consist of degraded keratin, amyloid P, and (secondary) immunoglobulin deposition.⁵⁰⁵ Mutations in two related genes, *OSMR* and *IL31RA*, are believed to be responsible for this condition. They are part of the interleukin-6 (IL-6) family of cytokine receptors. *OSMR* encodes oncostatin M receptor β , a component of the OSM type II receptor and the IL-31 receptor, whereas *IL31RA* encodes IL-31 receptor α , which, combined with OSR β , forms the IL-31 receptor. The ligand, IL-31, is a cytokine involved in several pruritic dermatoses.^{505,506} Transepidermal elimination of the papillary dermal deposits has been a characteristic feature.⁵⁰³

Secondary localized cutaneous amyloidosis

Secondary localized cutaneous amyloidosis refers to the finding of amyloid in the stroma of various cutaneous tumors, such as basal cell carcinoma (**Fig. 14.18**)⁵⁰⁷⁻⁵⁰⁹ and, less commonly, squamous cell carcinomas,⁵¹⁰ nevocellular nevi,⁵¹¹ trichoblastomas, cylindromas, pilomatrixomas, and syringocystadenoma papilliferum.⁵¹² Amyloid may underlie the epithelium in seborrheic and actinic keratoses,⁵¹³ Bowen's disease,⁵¹⁴ porokeratosis, skin treated with ultraviolet A radiation after the ingestion of psoralens (PUVA),⁵¹⁵ and mycosis fungoides.^{305,516,517} Amyloid has also been reported localized to areas of severe solar elastosis:⁵¹⁸ amyloid A protein was identified in this latter case. In all other circumstances, the amyloid appears to be of keratinocyte origin (AK).

Figure 14.18 Secondary amyloidosis. Hyaline deposits are present in the stroma of a basal cell carcinoma. (H&E)

Apolipoprotein E (apoE) is also a constituent of the amyloid deposits in both secondary localized and primary cutaneous amyloidosis.⁵¹⁹

PORPHYRIA

Porphyria is a metabolic disorder with varied cutaneous manifestations. It is considered in detail in Chapter 18, page 574.

The characteristic histological feature of the cutaneous porphyrias is the deposition of lightly eosinophilic, hyaline material in and around small blood vessels in the upper dermis. In erythropoietic protoporphyria, the hyaline material also forms an irregular cuff around these vessels, but it does not encroach upon the adjacent dermis as much as the hyaline material does in lipid proteinosis (see later). Furthermore, there is no involvement of the sweat glands in cutaneous porphyria. The hyaline material has similar staining characteristics in both diseases, although the hyaline material in porphyria tends to stain less intensely with Hale's colloidal iron method than it does in lipid proteinosis.

LIPID PROTEINOSIS

Lipid proteinosis, also known as Urbach–Wiethe disease and *hyalino-sis cutis et mucosae* (OMIM 247100), is a rare, autosomal recessive, multisystem genodermatosis that primarily affects the skin, oral cavity, and larynx, with the deposition of an amorphous hyaline material.^{520–527} The disease occurs worldwide, but it is more common in some geographical areas, such as areas of South Africa and Turkey.^{528,529} A gene founder effect has been proposed to explain the high number of cases in South Africa.⁵³⁰ The early clinical features are hoarseness and the development of recurrent skin infections, sometimes with vesiculobulbous lesions that heal leaving atrophic pock-like scars.^{531–533} Waxy papules and plaques develop progressively over several years on the face, scalp, neck, and extremities.⁵³⁴ Other features include beaded papules on the eyelid margins (blepharosis);^{535,536} oral ulceration;⁵³⁷ and verrucous lesions on the elbows, knees, and hands.⁵³⁸ A possible localized form, limited to hyperkeratotic lesions on both hands and wrists, has been reported.⁵³⁹ Although deposits have been found in many organs of the body, resulting dysfunction is rare.^{540,541} Insulin resistance has been reported in two adolescent siblings.⁵⁴² Epilepsy may be associated with calcification of the hippocampus.⁵³⁰

Lipid proteinosis results from mutations in the gene (*ECM1*) encoding extracellular matrix protein 1 on chromosome 1q21. More than 20 different mutations have been described,^{543,544} and it has been suggested that individuals with mutations in exon 7 have a milder phenotype than those with exon 6 mutations.⁵²⁸ Consanguinity is present in up to 20% of cases.^{529,545} The mechanism by which the mutations lead to excessive basement membrane deposition in skin and mucosae are poorly understood, but it has been suggested that a failure of mucocutaneous lymphangiogenesis may be the cause.⁵⁴⁶ Earlier work suggested it was a lysosomal storage disease.^{547,548} *ECM1* binds to the major heparan sulfate proteoglycan, perlecan, and functions as a 'biological glue' in the dermis, helping to regulate basement membrane and interstitial collagen fibril assembly.⁵⁴⁹ In the epidermis, *ECM1* plays a role in keratinocyte differentiation, which may be the cause of the warty hyperkeratosis found in this condition,⁵³⁰ although one study has shown that the absence of *ECM1* does not lead to alterations in epidermal maturation.⁵⁵⁰ Nevertheless, the finding of free-floating desmosomes in infants with vesicular lesions suggests a defect in the attachment of desmosomes to keratin filaments, probably a consequence of *ECM1* deficiency.⁵⁵¹

The deposited material has increased laminin and collagen of types IV and V and a relative decrease in collagen type I.^{552–557} There is also a selective increase in pro- $\alpha 1$ (IV)mRNA in lipid proteinosis.⁵⁵⁴

Limited success has been achieved by treating the disease with steroids, chloroquine, and etretinate. D-Penicillamine has also been used with some benefit.⁵⁵⁸

Histopathology^{559,560}

There is a progressive deposition of pale, eosinophilic, hyaline material in the superficial dermis, but this is initially localized around small blood vessels and at the periphery of eccrine sweat glands.⁵²¹ Small capillaries are sometimes increased in number. In advanced lesions, the deposits around blood vessels may have an 'onion-skin' appearance (Fig. 14.19). There is also progressive atrophy of secretory sweat glands associated with increasing hyaline deposition. This material is also deposited in arrector pili muscles and around pilosebaceous units. Calcification of the deposits is extremely rare.⁵⁴⁶ The epidermis may show hyperkeratosis and some acanthosis in the verrucous lesions.

The histology of the vesicular lesions has been described infrequently.^{561,562} There is extensive non-dyskeratotic acantholysis of the epidermis as well as a subepidermal cleft.⁵⁶¹ The superficial epidermis was absent in the erosive, vesicular lesions reported in one study.⁵⁶²

The hyaline deposits are PAS positive and diastase resistant (Fig. 14.20). They stain positively with colloidal iron and Alcian blue at pH 2.5 and also with Sudan black and oil red O on frozen sections.^{563,564} The accumulation of lipid is usually a late and presumably secondary phenomenon.^{563,565} Types IV and V collagen are increased at the dermoepidermal junction and around blood vessels.^{566,567}

Electron microscopy

In lipid proteinosis, there are fine collagen fibrils embedded in an amorphous, granular matrix.^{534,568–570} There is prominent reduplication of the basal lamina at the dermoepidermal junction and concentrically around vessels.^{552,555,570,571} Calcium deposits may be seen. Myofibroblasts have thick basal laminae in continuity with the hyaline masses.⁵⁷² Cytoplasmic inclusions have been noted in the fibroblasts; their exact significance is unknown.^{547,555} In blistering lesions, there is a dissociation of relatively intact desmosomes from keratinocytes, with desmosomes that are 'free-floating' in the intercellular spaces or attached by thin strands to the cell membrane.⁵⁵¹

Differential diagnosis

Although histologically and histochemically similar material is found in erythropoietic protoporphyria, the deposits in the latter condition are more limited in distribution, being perivascular only.⁵⁷³ Sweat glands are not involved in porphyria.

WALDENSTRÖM'S MACROGLOBULINEMIA

Translucent papules, formed by deposits of monoclonal IgM, are an uncommon manifestation of Waldenström's macroglobulinemia (see p. 1138). The hyaline deposits that fill the papillary and upper reticular dermis are strongly PAS positive (Fig. 14.21). The deposits encase blood vessels and hair follicles.⁵⁷⁴ Artifactual clefts may form. Ultrastructurally, the deposits are composed of fibrillar and granular material.⁵⁷⁵

COLLOID MILIUM AND COLLOID DEGENERATION

There are at least five distinct clinicopathological conditions that can be included under the umbrella term of 'colloid milium and colloid degeneration'.⁵⁷⁶ Regrettably, our knowledge of these conditions is limited by the paucity of reports in the literature. The five variants are as follows:

Figure 14.19 (A) Lipoid proteinosis. (B) Hyaline material is arranged around blood vessels in the papillary dermis in an onion-skin pattern. (H&E)

1. Colloid milium – classic adult type^{526,577–581}
2. Juvenile colloid milium⁵⁸²
3. Pigmented colloid milium (hydroquinone related)⁵⁸³
4. Colloid degeneration (paracoloid)⁵⁸⁴
5. Acral keratosis with eosinophilic dermal deposits.⁵⁸⁵

The *adult* type develops in early to mid-adult life with numerous yellow-brown, semitranslucent, dome-shaped papules, 1–4 mm or more in diameter. They may be discrete or clustered to form plaques. Verrucous lesions are rare.⁵⁸⁶ The cheeks, ears, neck, and dorsum of the hands are sites of predilection.⁵⁸⁷ Often, there is a history of exposure to petroleum products and/or excessive sunlight,^{580,588} but obviously there is some underlying predisposition as well.⁵⁸⁹ It has developed in a patient with β -thalassemia major.⁵⁹⁰ Unilateral involvement of the sun-exposed arm of taxi and truck drivers has been reported.^{591,592} The case reported on non-sun-exposed skin seems to be a different entity.⁵⁸¹ The material in the dermis is thought to represent a degeneration product of elastic fibers induced by solar radiation (actinic elastoid).^{593,594} Fractional photodermolysis produced clearance of facial lesions in one case of adult colloid milium.⁵⁹⁵

Juvenile colloid milium is exceedingly rare.^{582,596–599} Papules or plaques develop, usually on the face and neck, prior to puberty. Conjunctival and gingival involvement have been reported.^{600,601} A familial case has

been recently described.⁶⁰² It has been suggested that juvenile colloid milium and ligneous conjunctivitis are different clinical phenotypes of severe type 1 plasminogen deficiency.⁶⁰³ Some purported cases probably represent examples of erythropoietic protoporphyria.

*Pigmented colloid milium*⁵⁸³ is found as gray to black clustered or confluent papules on the face, following the excessive use of hydroquinone bleaching creams (see *ochronosis*, p. 445).

Colloid degeneration (paracoloid) presents as nodular, plaque-like areas, usually in chronically sun-exposed skin, particularly the face.^{584,604} This is probably a heterogeneous group as illustrated by the case occurring on penile skin.⁶⁰⁵

Acral keratosis with eosinophilic dermal deposits is the term used by Saeed, Sagatys, and Morgan for six cases that presented with agminated or solitary papules of the distal finger found on histological examination to contain amorphous eosinophilic deposits.⁵⁸⁵ The lesions were slowly progressive and had been present for 1–5 years. Only one patient had a history of chronic sun and hydrocarbon exposure. Their ages ranged from 59 to 81 years.⁵⁸⁵

Histopathology

In the *adult form*, there are nodular masses of homogeneous, eosinophilic material expanding the papillary dermis and extending into

Figure 14.20 Lipoid proteinosis. The hyaline material involving the papillary dermis and wall of blood vessels is PAS positive. (Periodic acid–Schiff)

the mid dermis (Fig. 14.22).⁵⁷⁸ Fissures and clefts divide this material into smaller islands, and fibroblasts are commonly aligned along the lines of fissuring (Fig. 14.23). A thin grenz zone of uninvolved collagen usually separates the colloid material from the overlying epidermis, which is thinned.⁶⁰⁶ Some clumped elastotic fibers are often present in this grenz zone and also between and below the colloid masses, but the colloid material itself stains only lightly or not at all with elastic stains.⁵⁹⁴ This material stains a ‘robin’s egg blue’ with Pinkus’ acid orcein–Giemsa method⁶⁰⁷ and has been reported to stain positively with crystal violet and Congo red and to give fluorescence with thioflavine T; such reactions are more likely to be positive on frozen than paraffin sections.^{578,606} Our own material (including a few cases using frozen sections) has not shown these reactions. In contrast to lipoid proteinosis and primary cutaneous amyloidosis, colloid milium does not contain laminin or type IV collagen.⁵⁹⁶

In the *juvenile form*, hypocellular material is present in the broadened dermal papillae; this shows some clefting with intervening spindle or stellate fibroblasts.⁵⁸² In most areas, there is no grenz zone and the basal layer may show hyaline transformation with a transition toward the dermal material. The hypocellular material may be accompanied by necrotic keratinocytes.⁶⁰² The colloid is PAS positive and sometimes

Figure 14.21 (A) Waldenström’s macroglobulinemia. Hyaline deposits fill the papillary dermis. (H&E) (B) They appear to be more extensive on special stains. (Periodic acid–Schiff) (Slides kindly provided by Dr. Richard Williamson)

Figure 14.23 Colloid milium. The clefted, hyaline material is hypocellular. (H&E)

methyl violet positive, but it is usually Congo red negative⁵⁹⁷ or weakly positive. Staining with crystal violet or cotton dyes is also negative.^{602,607} The material shows positivity with a polyclonal antibody to cytokeratin (MNf116).⁶⁰⁰ It is also positive for collagen IV and cytokeratin AE1/AE3.⁶⁰²

In the *pigmented form*,⁵⁸³ there are lightly pigmented colloid islands in the upper dermis (see p. 445).

In the *plaque type of colloid degeneration*,⁵⁸⁴ there is amorphous, homogenized, dermal collagen with small fissures and clefts extending deeply into the dermis (Fig. 14.24). It is relatively acellular. The material is basophilic or light pink in color,⁶⁰⁸ in contrast to the eosinophilic fissured material found in the case occurring on penile skin (discussed previously). It is weakly PAS positive but negative with Congo red and crystal violet. There is patchy staining with elastic tissue stains, but other areas are negative.

In *acral keratosis with eosinophilic dermal deposits*, there were variable degrees of hyperkeratosis and papillomatosis. An epidermal collarette was present in four of the six cases. The central epithelium was effaced by a sharply circumscribed deposit of amorphous eosinophilic material confined to the papillary dermis.⁵⁸⁵ The material was fissured in only one case. It had some resemblance to colloid degeneration,

particularly the case reported from the penis that was also eosinophilic (discussed previously). The material was trichrome positive and PAS positive with diastase resistance. Stains for amyloid, protein P, collagen type IV, and pan-keratin were negative. There was a conspicuous absence of elastic fibers in the deposits, similar to the findings in the case of colloid degeneration from the penis (discussed previously).

Electron microscopy

The ultrastructural features are different in the various types. In the adult form, there are large amounts of amorphous and granular material with some wavy, ill-defined, short, and branching filaments.^{606,609} Some components of actinic elastoid are present at the margins of the islands.³⁰⁵ There are active fibroblasts. In the juvenile form, there are fibrillary masses with some whorling, rare nuclear remnants, and some melanosomes and desmosomes.⁵⁸² Fibrillary transformation of keratinocytes has been observed, leading to the concept that the dermal tonofilament-like material is of epidermal origin.^{582,597} This has been confirmed by positive staining using a polyclonal antikeratin antibody.⁵⁹⁶ Colloid degeneration has shown microfilaments admixed with collagen, but more studies are needed before definite conclusions can be reached.

Figure 14.24 Colloid degeneration (paracolloid). The deposits extend more deeply than in colloid milium, and clefting is often less conspicuous. (H&E)

Differential diagnosis

Although on routine staining, the material deposited in juvenile colloid milium resembles that of adult colloid milium or colloid degeneration, the latter most likely derive from elastic tissue and/or other connective tissue elements. Therefore, in the latter conditions, an association with elastic fibers is often observed outright or can be inferred, with both H&E-stained sections and in tissues stained with the Verhoeff–van Gieson method or other elastin stains, and the colloid material is negative for keratins. As previously noted, keratin positivity also characterizes the deposits in macular and lichenoid amyloidosis. However, stains for amyloid are usually weak or negative in juvenile colloid milium. Although weak Congo red positivity has been described, immunostaining for amyloid P substance is negative.

MASSIVE CUTANEOUS HYALINOSIS

The term ‘massive cutaneous hyalinosis’ has been used to describe the condition of a patient with massive amorphous deposits of hyaline material in the deep dermis and subcutis of the face and upper trunk.⁶¹⁰ The material was PAS positive, Congo red negative, and ultrastructur-

Figure 14.25 (A) Triamcinolone injection site. (B) There is pale, foamy material surrounded by a palisade of macrophages. (H&E)

ally nonfibrillary.⁶¹⁰ Subsequent investigations have shown that there are three major components of this hyaline material: κ light chains, a mannose-rich glycoprotein, and type I collagen.⁶¹¹

CORTICOSTEROID INJECTION SITES

The local injection of corticosteroids into keloids or various soft tissue lesions results in a characteristic histological appearance should this site subsequently be biopsied.^{612–615}

Histopathology

There are usually well-defined, irregularly contoured lakes of lightly staining material in the dermis or deeper tissues.⁶¹³ The material is finely granular or amorphous and is surrounded by a variable histiocytic response, sometimes with a few admixed foreign body giant cells and lymphocytes (Fig. 14.25).⁶¹⁵ On low power, the material resembles to some extent that seen in gouty tophi after the crystals have been dissolved by formalin fixation. Crystal-shaped empty spaces may be seen within the material, and occasionally birefringent crystals have been present.⁶¹⁵ Sometimes there is no discernible reaction, whereas at other times a few neutrophils may be present. There is some controversy whether these differing appearances are time related.⁶¹⁵

The material may be weakly PAS positive, but although superficially resembling mucin, it does not stain for it.⁶¹⁴

A rheumatoid nodule-like appearance has been reported following corticosteroid injection.^{613,615} Transepidermal elimination of altered collagen has followed the intralesional injection of triamcinolone in areas of psoriasis.

HYALIN ANGIOPATHY (PULSE GRANULOMA)

Hyalin angiopathy is one term used for an entity that is also known as giant cell hyalin(e) angiopathy and pulse granuloma.^{616,617} It is an unusual histological change that has been reported in the oral cavity and skin.⁶¹⁸ All cutaneous cases have occurred in skin close to openings of the gastrointestinal tract.^{616,619} They are thought to represent an unusual foreign body reaction to implanted material. It is characterized by amorphous, eosinophilic material within and around blood vessels associated with acute or chronic inflammation. It does not stain for amyloid. Because the presence of giant cells is not always a conspicuous feature in the surrounding inflammatory reaction, it seems best not to refer to this condition as 'giant cell hyalin angiopathy'.⁶¹⁸ Proponents of the term pulse granuloma point out that the material is not always confined to the vascular surrounds.

INFANTILE SYSTEMIC HYALINOSIS AND JUVENILE HYALINE FIBROMATOSIS

Infantile systemic hyalinosis (OMIM 236490) and juvenile hyaline fibromatosis (OMIM 228600) are rare, autosomal recessive conditions characterized by multiple subcutaneous nodules, gingival hypertrophy, joint contractures, and hyaline deposits.⁶²⁰⁻⁶²³ They are allelic and characterized by pathogenic mutations in the capillary morphogenesis protein 2 (CMG2; also known as *ANTXR2*) gene on chromosome 4q21.^{620,624,625} Twenty-five different mutations of this gene had been reported as of 2012, including missense, nonsense, and splice-site mutations.⁶²⁶ The protein encoded by this gene is an integrin-like cell surface receptor for laminin and type IV collagen that may play a key role in cell-matrix or cell-cell interactions.⁶²⁴

In *infantile systemic hyalinosis*, the skin lesions are present at birth or appear in the first few months with hyperpigmented plaques over bony prominences.^{627,628} Pearly papules on the head and neck and fleshy nodules, particularly in the perianal region, then develop.^{620,624} There is failure to thrive; death occurs in early childhood.^{629,630}

Juvenile hyaline fibromatosis is characterized by papules, nodules, and large tumors on the hands, scalp, and ears that develop during the first few years of life.⁶³¹⁻⁶³⁴ There is also hypertrophy of the gingiva, flexural contractures, and often focal bone erosion.⁶³⁵⁻⁶⁴³ A localized form, with slow progression and no visceral involvement, has been reported.⁶⁴⁴ Spontaneous regression of tumors sometimes occurs. Recurrent infections may lead to death. There is elevated expression of matrix metalloproteinase-2 (MMP-2) and MMP-9, along with downregulation of decorin (a proteoglycan that regulates collagen fiber formation and remodeling) and upregulation of aggrecan (a chondroitin and keratan sulfate proteoglycan, most abundant in cartilage and also upregulated in the dermal fibroblasts of Hutchinson-Gilford syndrome).⁶⁴⁵

Histopathology

Both lesions are characterized by the deposition of an amorphous hyaline, eosinophilic substance in which spindle-shaped cells are embedded (Fig. 14.26). It may be vaguely chondroid.⁶⁴⁶ Basophilic calcospherules may form in the deposits.⁶⁴⁷ The material is PAS positive and diastase resistant.⁶⁴⁸ The matrix is more abundant in older lesions, whereas recent lesions tend to be more cellular.⁶²¹ The material

Figure 14.26 Juvenile hyaline fibromatosis. Small spindled cells, some of which are surrounded by clear spaces, are identified within a hyaline eosinophilic matrix. (H&E)

does not stain with Alcian blue.⁶⁴⁰ It lacks elastic fibers. A case with minimal hyaline change has been reported.⁶⁴⁹

Electron microscopy

The fibroblast-like cells have numerous single membrane vesicles containing fibrillogranular material.^{621,640,646,650} Similar material is found in the extracellular matrix.⁶²⁸ Collagen fibrils are also present.⁶⁴⁶

CYTOID BODIES

Cytoid bodies are ovoid, round or polygonal, discrete deposits that vary in size from 5 to 20 μm or more in diameter. The term has been applied to a heterogeneous group of deposits that include amyloid, colloid bodies, Russell bodies, and elastic globes.⁶⁵¹ With the exception of Russell bodies, which are derived from plasma cells, cytoid bodies are usually found in the papillary dermis.

Colloid bodies are derived from degenerate keratinocytes, usually associated with the lichenoid reaction pattern. They represent tonofilament-rich bodies extruded into the dermis, but they are sometimes trapped in the epidermis and are carried upwards with normal epidermal maturation. They are considered with the lichenoid tissue reaction in Chapter 3, page 38.

Elastic globes were first described in the 19th century and were for a time regarded as a diagnostic sign in cutaneous lupus erythematosus or scleroderma.⁶⁵¹ In 1965, Pinkus and colleagues described them in normal skin and suggested that they are a structural variant of elastic fibers.⁶⁵² They can be found regularly in clinically normal skin from the face and extremities, particularly the calf. It has been suggested that elastic globes in some circumstances may represent the end stage of degenerated colloid bodies; this has not been confirmed by immunohistochemistry, which shows that elastic globes have an immunological profile similar to that of elastic fiber microfibrils.⁶⁵³

Histopathology^{651,654}

Elastic globes are usually amphophilic, PAS-positive structures found in the papillary dermis (see p. 391). They may have a slight basophilic tint in sun-damaged skin. They are usually larger than cell size (Fig. 14.27), stain strongly with elastic tissue stains, and are weakly autofluorescent.

Figure 14.27 Elastic globes in the papillary dermis. (H&E)

Electron microscopy

Electron microscopy shows electron-dense, granular, amorphous, and filamentous material.

PIGMENT AND RELATED DEPOSITS

A heterogeneous group of exogenous and endogenous pigments may be found in the skin. For convenience, the various heavy metals and drugs that produce deposits and/or pigmentary changes are discussed here as well.

For completeness, note that the shaving heads and foils used in electric shavers may be a daily source of iron–chromium–nickel contamination of the skin, leading theoretically to allergic reactions.⁶⁵⁵ Deposits of iron, nickel, and chromium have been reported in the skin following total elbow arthroplasty.⁶⁵⁶ The metallosis produced blue-gray pigmentation of the forearm.⁶⁵⁶ Unidentified pigment deposits have also been reported in the skin following a high-pressure paint-gun injury of a finger; the reaction simulated a giant cell tumor of tendon sheath.⁶⁵⁷ Traumatic osmium tetroxide inoculation can result in gray-brown staining to elastic tissue and amorphous gray-brown deposits.⁶⁵⁸

Yellow-orange macular discoloration of the skin (xanthoderma) may be produced by jaundice, carotenoderma, ‘tanning pills’ and sprays, and several drugs. This topic was reviewed in 2007.⁶⁵⁹

OCHRONOSIS

Ochronosis refers to the yellow-brown or ocher pigment (homogentisic acid) deposited in collagen-containing tissues in alkaptonuria.^{660,661} Alkaptonuria (OMIM 203500) is an autosomal recessive disorder in which the hepatic and renal enzyme homogentisic acid oxidase is absent.^{662–667} The gene responsible (*HGD*) maps to chromosome 3q21–q23. The term ochronosis is also used for the deposition of similar hydroquinone derivatives in certain exogenously induced conditions that sometimes followed the topical use of phenol in the treatment of leg ulcers and of picric acid in the treatment of burns (both procedures have now been abandoned) and that are still seen as a complication of the oral administration^{668,669} or intramuscular injection⁶⁷⁰ of antimalarial drugs and the topical use of hydroquinone bleaching creams in black

Figure 14.28 Ochronosis. An irregularly shaped deposit is present in the mid dermis. (H&E)

racés.^{671–682} The author has also seen it in a patient who consumed large quantities of quinine-containing tonic water.

There is some clinical variability in the presentation of the various types. In alkaptonuria, there is bluish and bluish-black pigmentation of the face, neck, dorsum of the hands, and palmoplantar region^{683,684} and bluish discoloration of the sclerae and of the cartilage of the ears and sometimes of the nose.⁶⁸⁵ Acrokeratoelastoidosis-like lesions were present in one case.⁶⁸⁶ In the pigmentation associated with antimalarial therapy, the pretibial, palatal, facial, and subungual areas have been involved.⁶⁸⁷ In hydroquinone-induced lesions, the face (particularly the malar areas), neck and sometimes the ears, corresponding to sites of application of the cream, are involved.⁶⁸⁸ The dorsal aspect of the interphalangeal joints is frequently affected.⁶⁸⁹ There is hyperpigmentation, with variable development of finely papular and even colloid milium-like areas.^{671–673} Skin atrophy, striae, and acne also develop.^{689–692} Of interest is the complete absence of hydroquinone-induced ochronosis in areas of vitiligo.⁶⁹³ This suggests that melanocytes are necessary for the deposition of the pigment, which is presumably derived from a melanin–hydroquinone precursor.⁶⁹³

Histopathology^{672,685}

There is a marked similarity between the ochronotic deposits in alkaptonuria and hydroquinone-induced ochronosis.⁶⁷³ In the earliest stages, there is some basophilia of the collagen fibers in the upper dermis, followed by the appearance of stout, sharply defined, ocher-colored fibers that may be crescentic, vermiform, or banana-shaped (Fig. 14.28).⁶⁷² Fragmented fibers and small pigmented deposits may also be present, the latter lying free in the dermis or in macrophages. Pigment granules are also found in the endothelial cells of blood vessels and the basement membrane of sweat glands.⁶⁶³ Colloid milium-like foci often develop in the hydroquinone-induced lesions, and these foci may show no visible ochronotic material or only partial staining of the fibers.⁶⁷² Transepidermal elimination of ochronotic fibers has been observed.^{683,694} A variable number of macrophages are present, but they are usually infrequent in alkaptonuria. Rarely, foreign body giant cells surround the fibers, but this occurs more often in extracutaneous sites.⁶⁶⁴ Actinic granuloma-like changes have also been reported (see p. 212).⁶⁹⁵

In hydroquinone-induced pigmentation, there is usually diminution in basal melanin but prominent melanin in macrophages in the papillary dermis. In lesions induced by antimalarial drugs, the changes are usually different, with small pigment granules that are predominantly

in macrophages in a perivascular position and around appendages.^{668,687} Small ocher-colored fibers can be present throughout the dermis, but large fibers in the upper dermis are not a feature. The pigment in the antimalarial-induced cases usually stains positively for melanin and hemosiderin,⁶⁶⁸ whereas in the other forms the fibers and smaller deposits are usually negative with these stains and also with elastic tissue stains.⁶⁷² They do, however, stain darkly with methylene blue.⁶⁷³

Dermoscopic findings of exogenous ochronosis include brown-gray globular, arciform or annular structures,^{696,697} and reflectance confocal microscopy shows nonrefractile, banana-shaped structures.⁶⁹⁶

Electron microscopy

The ochronotic deposits are electron dense. They are usually homogeneous⁶⁷³ but may be fibrillar.⁶⁶² There is granular, less electron-dense material at the periphery with fibroblasts investing and ramifying through it.⁶⁷² In exogenous ochronosis, the electron-dense material is also found in the core of elastic fibers, and elastic tissue degenerative changes are identified.⁶⁹⁶ Active phagocytosis of electron-dense material is present.⁶⁷³

TATTOOS

Tattoos are produced by the mechanical introduction of insoluble pigments into the dermis. In one telephone study reported from the United States, 24% of respondents had tattoos,^{698,699} while an almost identical incidence was obtained in a survey of university undergraduates.⁷⁰⁰ Most tattoos are decorative in type, but occasionally carbon or some other pigment is traumatically implanted in an industrial or firearm accident.^{701,702} The incidence of complications is becoming quite rare with the declining use of mercury salts (although other red tattoo pigments may cause reactions)^{703,704} and a greater emphasis on hygiene in tattoo parlors.

The complications have been well reviewed.^{705–707} They may be grouped into several broad categories: infections introduced at the time of tattooing; cutaneous diseases that localize in tattoos, often in a Koebner-type phenomenon; allergic reactions to the tattoo pigments;⁷⁰⁸ photosensitivity reactions;^{707,709} tumors; and miscellaneous reactions. The infections reported have included pyogenic infections, syphilis, leprosy, tuberculosis,⁷¹⁰ tetanus, chancroid, verruca vulgaris,^{706,711–714} vaccinia, herpes simplex and zoster, molluscum contagiosum,⁷¹⁵ viral hepatitis, and a dermatophyte infection.⁷¹⁶ Cutaneous diseases that may localize in tattoos include psoriasis, lichen planus,⁷¹⁷ Darier's disease, and discoid lupus erythematosus, the latter in the red areas.⁷⁰⁷ Allergic reactions can occur to mercury,⁷¹⁸ chromium,^{719,720} manganese,⁷²¹ aluminum,⁷²² cobalt, and cadmium salts.^{707,723,724} Photosensitivity reactions may be photoallergic or phototoxic, with the latter reaction being quite common with cadmium sulfide, a yellow pigment.⁷²³ A granulomatous reaction to an old cosmetic tattoo followed intense pulsed light treatment for facial skin rejuvenation.⁷²⁵ The development of tumors such as basal cell^{726,727} and squamous cell carcinomas, melanoma, keratoacanthoma, lymphoma,⁷²⁸ and reticulohistiocytoma may well be coincidental.⁷⁰⁵ Miscellaneous lesions include keloids,⁷⁰⁶ regional lymphadenopathy, and a sarcoidal reaction that may be localized or systemic.^{729–731}

Temporary henna tattoos are becoming more popular, especially among teenagers.⁷³² Allergic and irritant reactions have been reported, but most reactions occur when henna is used in combination with other coloring agents.^{732–737} Another recent fad has been the use of cosmetic tattooing (permanent makeup) applied to the lips, eyelids, and eyebrows. Complications have been reported.⁷³⁸

Experimental work with guinea pigs suggests that the lightening of tattoos after laser therapy results more from widespread necrosis and subsequent tissue sloughing and dermal fibrosis than from any specific

Figure 14.29 Tattoo. Black pigment is seen in macrophages and lying free in a predominantly perivascular location. (H&E)

changes in the pigment or its handling by macrophages.⁷³⁹ Other mechanisms appear to be involved with some of the newer lasers.^{740–742} Some tattoo inks can be difficult to remove.^{743,744} The presence of titanium dioxide in the inks is associated with a poor response to laser therapy.⁷⁴⁵ Topical tacrolimus has been used successfully to treat a lichenoid tattoo reaction,⁷⁴⁶ and etanercept has been used successfully to treat a granulomatous reaction.⁷⁴⁷ Tattoo removal using traditional therapy may result in adverse reactions.⁷⁴⁸

Histopathology⁷⁴⁹

Tattoo pigments are easily visualized in tissue sections. After several weeks, they localize around vessels in the upper and mid dermis in macrophages and fibroblasts (**Fig. 14.29**). Extracellular deposits of pigment are also found between collagen bundles. The pigment is generally refractile but not doubly refractile. A foreign body granulomatous reaction has not been recorded except in the presence of other severe reactions.

Hypersensitivity reactions in tattoos vary from a diffuse lymphohistiocytic infiltrate in the dermis (**Fig. 14.30**), with an admixture of some plasma cells and eosinophils, to a lichenoid reaction,^{750–752} sometimes with associated epithelial hyperplasia.^{724,753,754} Red tattoo pigment is often implicated in producing lichenoid reactions.^{741,755} A lichenoid reaction has also been reported following a temporary tattoo containing henna and *p*-phenylenediamine.⁷³⁶ Other reactions include the development of sarcoidal granulomas, a granuloma annulare-like reaction, a vasculitis,^{756,757} and a pseudolymphomatous pattern.^{753,758–761} Scarring may be present. A morphea-like reaction developed in one case.⁷⁶² Epidermal spongiosis and pseudoepitheliomatous hyperplasia have been reported.^{749,763} The occurrence of a compound melanocytic nevus along the ink lines of a tattoo was hypothesized as being due to multiple autografts of nevus cells from a pre-existing benign nevus, during the creation of the tattoo.⁷⁶⁴

The pigment deposits that are traumatically implanted in the skin during an industrial or other accident are usually more variable in size and often larger than the deposits introduced in decorative tattoos (**Fig. 14.31**). Sometimes, the pigment in accidental tattoos is found in the mid dermis.

Recently, attempts have been made to correlate the ultrastructural features with the pigment used, as determined by X-ray microanalysis techniques.⁷⁶⁵ The pigment present in macrophages may be granular or crystalline.⁷⁶⁵ It is sometimes membrane bound. Tattoo pigment has also been found in dermal fibroblasts.⁷⁶⁶

Figure 14.30 Tattoo pigment with an associated inflammatory reaction, the result of an allergic reaction to one of the pigments. (H&E)

HEMOCHROMATOSIS

Hemochromatosis is a multisystem disorder of iron metabolism in which cutaneous pigmentation is a manifestation in up to 90% of patients ('bronzed diabetes').^{767,768} Although generalized, the pigmentation is most obvious on the face, especially the forehead and malar areas.⁷⁶⁸ Some patients have been reported to have a slate-gray color, rather than the typical bronze pigmentation.⁷⁶⁸ Cutaneous pigmentation fades slowly with venesection of the patient.

The bronze color results from increased melanin in the basal layers of the epidermis and, to a lesser extent, some coexisting thinning of the epidermis.⁷⁶⁷ Patients with a slate-gray color have been reported to show hemosiderin deposits in the epidermis as well as the dermis, and it is assumed that the epidermal hemosiderin contributes to the skin color in these patients.⁷⁶⁸ The absence of pigmentation in the vitiliginous areas of patients with both vitiligo and hemochromatosis indicates that hemosiderin in the usual dermal sites does not contribute significantly to the bronze color in patients with hemochromatosis.⁷⁶⁹ Pigment changes are not as apparent in dark-skinned races, although the darkening of pre-existing epidermal

Figure 14.31 Nondecorative tattoo. The coarse deposits were impregnated into the skin in a work injury. They are more variable in size than the pigment in a decorative tattoo. (H&E)

cysts, due to increased melanin in their walls, or of keloids may be a useful marker.⁷⁷⁰

The increased melanin production is thought to result from the deposition of hemosiderin in the skin, as other heavy metals will produce a similar response. The mechanism by which the heavy metals stimulate melanin production is uncertain.

Histopathology^{767,771}

There may be some thinning of the epidermis and increased melanin pigment in the basal layer. Golden brown granules of hemosiderin are present in the basement membrane region of the sweat glands and in macrophages in the loose connective tissue stroma of these glands. A small amount can often be seen associated with sebaceous glands and their stroma. In some cases, small specks of hemosiderin can be seen in the epidermis with Perls' stain.^{768,772}

HEMOSIDERIN FROM OTHER SOURCES

Hemosiderin has also been noted in the skin following the application of Monsel's solution (20% aqueous ferric subsulfate) for hemostasis in minor surgical procedures⁷⁷³⁻⁷⁷⁵ and the use of iron sesquioxide on a skin ulcer.⁷⁷⁶ In both circumstances, there has been ferrugination of collagen fibers with numerous siderophages^{774,775} and sometimes multinucleate giant cells⁷⁷⁶ in the interstitial tissues of the dermis. Perls' stain has been strongly positive in these areas.

Hemosiderin is conspicuous in venous stasis of the lower legs.⁷⁷⁷ It is found in the pigmented purpuric dermatoses, Zoon's balanitis and Zoon's vulvitis, granuloma faciale, and the pigmented pretibial patches of diabetes mellitus. Impregnation of iron from earrings and metallic foreign bodies has been reported.⁷⁷⁸⁻⁷⁸⁰ Ferruginous foreign bodies may be clinically mistaken for melanomas.⁷⁷⁹ Hemosiderin is also present around glass fragments in the dermis (Fig. 14.32), and in dermatofibromas and various tumors of blood vessels.

'BRONZE BABY' SYNDROME

'Bronze baby' syndrome refers to the transient bronze discoloration of the skin, serum, and urine that is a relatively uncommon complication

Figure 14.32 Hemosiderin deposits around fragments of glass in the dermis. (H&E)

of phototherapy for neonatal hyperbilirubinemia.^{780,781} The pigment is thought to be either a photo-oxidation product of bilirubin or a copper-bound porphyrin; it may even be biliverdin.⁷⁸² No histological studies have been undertaken.

Localized green discoloration of the palms and soles has been reported in an adult with hyperbilirubinemia.⁷⁸³

SILVER DEPOSITION (ARGYRIA)

Argyria, which refers to the systemic deposition of silver salts, is an iatrogenic disease resulting from the indiscriminate ingestion of silver-containing compounds or their application to mucous membranes or burnt skin.^{784–787} Now that the availability of these preparations is restricted, argyria should be rare and seen only in relation to industrial exposure.⁷⁸⁸ However, bizarre dietary fads and the availability of colloidal silver preparations on the Internet as part of alternative health treatments have led to a resurgence in the incidence of this disease.^{789–796}

Cutaneous changes of argyria consist of permanent blue-gray pigmentation, resembling cyanosis, which is most marked in sun-exposed areas.⁷⁹⁷ The nail lunulae may be azure blue.^{797,798} The pigmentation is thought to result from the photoactivated reduction of the absorbed silver salts to metallic silver.^{789,799} There is probably some contribution from increased melanin production as well.

Localized argyria has been reported after prolonged topical exposure,^{800,801} at the site of implanted acupuncture needles,^{802–804} and from the wearing of silver earrings in pierced ears.⁸⁰⁵

Histopathology⁷⁸⁴

There are multiple, minute, brown-black granules deposited in a band-like manner in relation to the basement membranes of sweat glands. They are also found in elastic fibers in the papillary dermis and, to a lesser extent, in the connective tissue sheaths around the pilosebaceous follicles (Fig. 14.33), in the arrector pili muscles, and in arteriolar walls. On dark-field examination, the deposits are more easily detected, giving a ‘stars in heaven’ pattern (Fig. 14.34).⁸⁰⁶ In one case of localized argyria, the deposits were in the papillary dermis adjacent to the intraepidermal sweat duct.⁸⁰⁰ Localized argyria may also present with ocher-colored, swollen, and homogenized collagen bundles resembling those seen in ochronosis.⁸⁰⁷ There is usually an increase in melanin

Figure 14.33 Argyria. There are fine silver particles along the connective tissue sheath of the hair follicle (arrow). The patient worked in a silver mine. (H&E)

Figure 14.34 Argyria, dark-field microscopy. Brightly refractile silver deposits can be seen surrounding eccrine sweat glands.

pigment in the basal layer of the epidermis, and melanophages are present in the papillary dermis.

Scanning electron microscopy has shown that the granules are larger and more abundant in exposed than nonexposed skin.⁷⁸⁹ Transmission electron microscopy shows electron-dense bodies 13–1000 μm in diameter in relation to sweat glands and the microfibrils of elastic fibers.^{790,806,808,809} The granules are found in macrophages in membrane-bound aggregates.^{789,790} Histochemical studies suggested that the deposits were in the form of silver sulfide,⁸¹⁰ the recent use of X-ray probe microanalysis has confirmed the presence of silver and sulfur, with the addition of selenium and other metals in trace amounts.^{784,790}

Rarely, silver nitrate staining of the skin may be mistaken for a melanocytic lesion and removed. The author has seen such a case involving a colleague (Fig. 14.35).

Dermoscopy of argyria shows blue-gray dots, annular structures, and streaks (silver deposits) across a yellow background (the grenz zone of uninvolved papillary dermal collagen). This differs from the homogeneous blue areas, globules, or red pigment or streaks seen in melanocytic lesions.⁸¹¹

Figure 14.35 Silver nitrate pigmentation of the stratum corneum. This lesion was removed because of clinical suspicion of a melanoma. (H&E)

GOLD DEPOSITION (CHRYSIASIS)

Chrysiasis refers to the permanent blue-gray pigmentation of the skin, most pronounced in sun-exposed areas, which results from the deposition of gold salts in the dermis, following gold injections for the treatment of rheumatoid arthritis and pemphigus.^{784,812–815} Its development is, in part, dose related, but light exposure and even laser therapy appear to favor its deposition.^{816–819}

Besides chrysiasis, gold injections may produce a nonspecific eczematous or urticarial reaction, eruptions resembling lichen planus and pityriasis rosea and, rarely, erythema nodosum or erythroderma.^{820,821}

Histopathology^{784,816,822}

Small round or oval black granules, irregular in size, are present in dermal macrophages that tend to localize around blood vessels in the upper and mid dermis. Similar pigment may be in elongated, fibroblast-like cells in the upper dermis.⁸¹³ The gold is well visualized on dark-field examination. A striking orange-red birefringence can be demonstrated under polarized light.⁸²³ The granules are larger than silver granules and, unlike argyria, there is no deposition of gold on membranes.

Electron microscopy

Electron microscopy shows electron-dense particles in phagolysosomes of macrophages.^{813,824} The appearances vary with the method of staining used.⁸²⁵

MERCURY (HYDRARGYRIASIS)

Now that mercury-containing ointments are no longer commonly used, the slate gray pigmentation of the skin related to the topical application of mercury salts is rarely seen.^{812,826–829} Another manifestation of mercury intoxication that is rarely seen is acrodynia (pink disease), a condition of early childhood attributed to chronic mercury ingestion in teething powders.^{830,831} Acral parts assume a dusky pink color. Serious systemic symptoms and even death sometimes ensue. Cutaneous nodules containing globules of mercury have been reported in one patient, as a reaction to oral mercury.⁸³² With the increasing consump-

tion of mercury-polluted seafood, papular and papulovesicular eruptions are being seen.⁸³³

A widespread allergic reaction (mercury exanthem) may follow exposure to high concentrations of mercury vapor⁸³⁴ or the topical application of mercury-containing ointments.⁸³⁵ Local sclerosing granulomatous lesions may follow the implantation of mercury associated with skin trauma from a broken thermometer,⁸³⁶ self-injection,⁸³⁷ or temporary henna tattoos.⁸³⁸

Histopathology^{827,837,839}

The pigmentation from topical applications of mercurial preparations results from the deposition of brown-black mercury granules in aggregates of up to 300 μm in macrophages around blood vessels in the upper dermis and in linear bands following the course of elastic fibers.⁷⁸⁴ The particles are refractile. There may be a contribution from increased melanin in the basal layer.⁸⁴⁰

The mercury exanthem shows subcorneal neutrophilic microabscesses with a variable perivascular neutrophilic and lymphocytic infiltrate around vessels in the upper dermis.

The accidental or deliberate implantation of mercury into the skin results in a granulomatous foreign body giant cell reaction.^{837,841} A zone of degenerate collagen often surrounds the black spherules of mercury in the tissues.^{836,837,842} In older lesions, there may be fibrosis around the deposits.⁸³⁶ Ulceration or pseudoepitheliomatous hyperplasia may overlie dermal deposits of mercury.

Electron microscopy

Particles averaging 14 nm in diameter, but forming larger aggregates, are present in the dermis.

Differential diagnosis of argyria, chrysiasis, and hydrargyriasis

The characteristics of the granules in these conditions distinguish the pigmentation they produce from that due purely to melanin or to pigment-producing drugs such as minocycline, phenothiazines, or anti-malarials, which may variably include melanin, a melanin-like drug metabolite, or iron. With light microscopy, it may be difficult to distinguish among gold, silver, and mercury deposits. All are refractile on dark-field microscopy. However, gold granules are larger and more irregular than those of silver and are found predominantly within macrophages. Silver particles are largely extracellular and tend to be deposited on basement membranes, around vessels, and on elastic fibers. Mercury granules are also found most commonly in macrophages or occasionally in the epidermal basilar layer. The orange-red birefringence of gold particles with cross-polarized light may be a unique feature. Further distinction can be made with ultrastructural study, based on not only the distribution but also the relative size of the granules (gold is larger than silver; silver is larger than mercury) and their aggregation properties. If necessary, X-ray microanalysis and related methods can provide definitive identification of the material.

ARSENIC

Prolonged ingestion of arsenic may result in a diffuse, macular, bronze pigmentation, most pronounced on the trunk with 'raindrop' areas of normal or depigmented skin.⁷⁸⁴ The color is said to arise partly from increased melanin in the basal layer and partly from the metal itself. Other manifestations of chronic arsenical poisoning include keratoses, hyperkeratosis of the palms and soles, and carcinomas of the skin. Periungual pigmentation developed in some of the survivors of an incident involving the ingestion of arsenic-laced curry at a community festival.⁸⁴³ In the acute stage, facial edema, flushing, and conjunctival hemorrhages were common.⁸⁴³

LEAD

Lead poisoning may result in a blue line at the gingival margin due to the subepithelial deposit of lead sulfide granules.^{784,844}

ALUMINUM

Persistent subcutaneous nodules are a rare complication of the use of aluminum-adsorbed vaccines in immunization procedures.⁸⁴⁵⁻⁸⁴⁷ The nodules may be painful or pruritic.^{845,846} Aluminum salts used in tattooing rarely cause a granulomatous reaction in the skin.⁷²² An aluminum 'tattoo' can also result from the use of topical aluminum chloride in the cauterization of biopsy sites and from the insertion of a dental prosthesis.^{848,849} Drysol® (aluminum chloride) is now being used as a hemostatic agent for minor surgical procedures.⁸⁵⁰ Contact sensitivity, and a pseudolymphomatous reaction at vaccination sites due to aluminum-containing vaccines, has also been reported.^{851,852} Speckled pigmentation of the lower legs has been reported following the implantation of metallic particles in the skin associated with welding.⁸⁵³ Aluminum was one of several different metals present.

Histopathology^{847,854}

The nodular lesions show a heavy lymphoid infiltrate in the lower dermis and subcutis with well-formed lymphoid follicles, complete with germinal centers. The infiltrate around the follicles includes lymphocytes, plasma cells, and sometimes eosinophils. Macrophages with slightly granular cytoplasm that stains purple-gray with H&E are usually present.⁸⁴⁶ Giant cells and small areas of necrosis are sometimes seen. The aluminum can be confirmed by X-ray microanalysis⁸⁴⁶ or by the solochrome-azurine stain in which crystals of aluminum salts stain a deep gray-blue color.

Aluminum 'tattoos', following the topical application of aluminum chloride, contain variable numbers of macrophages with ample stippled cytoplasm, resembling the parasitized macrophages of certain infectious diseases. However, the particles are larger and more variable in size than parasites.⁸⁴⁸ An underlying scar is usually present. Following the use of Drysol®, there are individual and clusters of macrophages with abundant cytoplasm. They contain aluminum.⁸⁵⁰

ZINC

Zinc deposition has been reported on the lip, following the use of a zinc oxide-containing sunblock for a period of several days.⁸⁵⁵ It presented as a well-demarcated dark black macule with an uneven edge. Histological examination showed the submucosal deposition of fine golden yellow granules, predominantly in a superficial location and in a linear fashion upon the extracellular matrix, especially on elastic fibers.⁸⁵⁵ Some concentration of the zinc granules was also seen around blood vessels.

BERYLLIUM

Beryllium is one of the lightest metals, and it is used as an alloy with other metals. Pulmonary granulomas are a serious complication of prolonged industrial exposure. Although it does not produce cutaneous deposits, it is included here because it produces irritant contact dermatitis, allergic contact dermatitis, chemical ulcers, ulcerating granulomas, and allergic granulomas.⁸⁵⁶ The granulomas are usually confluent and sarcoidal in type with some central fibrinoid necrosis.⁸⁵⁶

BISMUTH

Generalized pigmentation resembling argyria may follow systemic use of bismuth. Metallic granules are present in the dermis.⁷⁸⁴ Crops of small black carbon-like particles have been reported on the skin after prolonged ingestion of a bismuth subsalicylate preparation.⁸⁵⁷ It has been suggested that prurigo pigmentosa, a condition seen mostly in Japan, is a persistent lichenoid reaction to bismuth with postinflammatory melanin incontinence and pigmentation of the skin.⁸⁵⁸

TITANIUM

Exposure to titanium dioxide may produce cutaneous lesions.^{859,860} There is one report of a patient developing small papules on the penis following the application of an ointment containing titanium dioxide for the treatment of herpetic lesions.⁸⁵⁹ Another report of occupational exposure documents involvement of the lungs, skin, and synovium.⁸⁶⁰ In the case involving topical application, numerous brown granules, confirmed as titanium by electron probe microanalysis, were present in the upper dermis, both free and in macrophages.⁸⁵⁹ In another case, a necrotizing lesion involving the subcutis, with extension into muscle, was present.⁸⁶⁰ Granulomatous reactions to a titanium alloy used in ear piercing and to titanium screws in a hip replacement have also been reported.^{861,862}

DRUG DEPOSITS AND PIGMENTATION

A number of mechanisms are involved in the cutaneous pigmentation induced by certain drugs, including an increased formation of melanin; the deposition of the drug or complexes derived therefrom in the dermis; and postinflammatory pigmentation, with melanin incontinence, usually following a lichenoid reaction.^{812,863} The exact mechanism is still unknown in many cases. Therefore, drugs share many features with the heavy metals already considered. This subject has been well reviewed.⁷⁸⁴

Antimalarial drugs

The long-term use of antimalarial drugs, either for malarial prophylaxis or in the treatment of various collagen diseases and dermatoses, can result in cutaneous pigmentation.⁸⁶⁴ Several patterns are seen.^{784,865} Yellow pigmentation is sometimes seen with quinacrine (mepacrine), although the histopathology has not been described. Small ochronosis-like deposits are a rare finding. Pretibial pigmentation is more common, and this is slate gray to blue-black in color. Pigment granules – some staining for hemosiderin, some for melanin, and some for both – can be seen in macrophages and extracellularly.⁶⁸⁷

Phenothiazines

Prolonged use of phenothiazines produces a progressive gray-blue pigmentation in sun-exposed areas.⁸⁶⁶ Slow fading occurs with cessation of the drug.⁸⁶⁷ Similar cutaneous pigmentation has been reported in patients taking imipramine⁸⁶⁸⁻⁸⁷² and in one taking desipramine.⁸⁷³ Refractile, golden-brown pigment with the staining properties of melanin is found in the dermis along collagen bundles and in macrophages, especially around vessels in the superficial vascular plexus (**Fig. 14.36**).^{784,870} The Perls' method for iron is negative. Electron microscopy shows melanin granules in macrophages but also other bodies of varying electron densities that may represent metabolites or complexes of the drug.^{874,875}

Figure 14.36 Phenothiazine pigmentation. Refractile, golden-brown pigment is seen in the dermis, along collagen bundles, and in macrophages. (H&E)

Tetracycline

Bluish pigmentation of cutaneous osteomas, and bluish-green pigmentation in areas of trauma on the lower legs, has resulted from the use of tetracycline.^{876,877} Rarely, pigmentation of acne scars on the face occurs.⁸⁷⁸ The use of doxycycline in suprapharmacological doses (by a psychotic patient) resulted in cutaneous hyperpigmentation resembling that seen with minocycline.⁸⁷⁹

Methacycline

The prolonged use of the antibiotic methacycline produces gray-black pigmentation of light-exposed areas and some conjunctival pigmentation in a small percentage of patients.⁷⁸⁴ In addition to increased melanin in the basal layer of the epidermis, there is extracellular pigment in the elastotic sun-damaged areas that stains positively with the Masson–Fontana method for melanin.⁸⁸⁰ Some of this pigment is in macrophages.

Minocycline

Five different patterns^{881,882} of cutaneous pigmentation may follow long-term therapy with the antibiotic minocycline:

- Type I Bluish-black pigmentation of scars^{883,884} and old inflammatory foci, including sites of immunobullous diseases,⁸⁸⁵ related to hemosiderin or an iron chelate of minocycline; a variant of this (proposed type IV), with blue-gray pigmentation of acne scars on the back, was characterized by calcium-containing melanin deposits within dendritic cells and in an extracellular location⁸⁸⁶
- Type II Blue-gray circumscribed pigmentation of the lower legs and arms due to a pigment that is probably a drug metabolite–protein complex chelated with iron and calcium. The reported cases with deposits of minocycline pigment localized to the subcutaneous fat of the lower extremity appear to be a different type (proposed type V)^{887,888}
- Type III A generalized muddy brown pigmentation due to increased melanin in the basal layer and accentuated in sun-exposed areas.^{886,889}

Figure 14.37 Minocycline pigment deposited on dermal elastic fibers. (Masson–Fontana)

Combinations of these patterns are not uncommon.⁸⁸⁶ Blue perspiration has also been reported.⁸⁹⁰ In patients with atopic dermatitis, diffuse cutaneous pigmentation results from relatively short-term minocycline therapy, 3–28 days.⁸⁹¹

A case involving the lips and one involving the tongue have been reported.^{892,893} The sclerae may be involved in severe cases.⁸⁹⁴ ‘Black bone disease’ has also been reported from long-term minocycline use.⁸⁹⁵ Rare cases of P-ANCA-positive cutaneous polyarteritis nodosa have been reported as a possible complication of minocycline therapy.⁸⁹⁶

The pigmentation in all cases gradually fades after cessation of the drug.^{885,897} Laser therapy has been used in cases of incomplete disappearance of the pigmentation.⁸⁹⁸

Histopathology^{784,882}

The pigment in the localized types is present in macrophages, often aggregated in perivascular areas, in dermal dendrocytes,⁸⁹⁹ and in eccrine myoepithelial cells.⁹⁰⁰ In other cases, the pigment may deposit on elastic fibers or lie free in the dermis.⁹⁰¹ It has also been seen in a localized capillaritis of the legs.⁹⁰² This complex pigment is positive with both the Perls’ method for iron and the Masson–Fontana method for melanin (Fig. 14.37), but it is negative with the PAS stain.⁹⁰³ Iron was absent from the deposits in the proposed type IV pigmentation of acne scars (discussed previously).⁸⁸⁶ It has also been absent from cases in which minocycline pigmentation was isolated to the subcutaneous fat of the lower extremity.^{887,888} Green-gray, flocculent, nonrefractile globules were present in macrophages in the subcutis in these cases.⁸⁸⁸ It is non-birefringent and nonfluorescent.

Electron microscopy

There are intracytoplasmic granules of dark homogeneous material and small fine particles containing iron.^{882,904–906}

Amiodarone

Amiodarone, an iodinated benzofuran derivative used in the treatment of cardiac arrhythmias, produces slate-gray discoloration of sun-exposed areas in patients on prolonged high-dose therapy.^{907–911} It affects 1–2% of those taking the drug.⁹¹¹ Cutaneous photosensitivity is a more common complication of the drug.⁹⁰⁸ The pigmentation slowly disappears after cessation of the drug.⁹⁰⁸ Basal cell carcinoma has been reported after amiodarone therapy, but this may be a chance association.⁹¹² Brown granules, staining positively with the

Figure 14.38 Amiodarone pigmentation. Yellow-brown granules are found in macrophages in the mid dermis. Although generally believed to be lipofuscin, recent evidence suggests that the material may in fact represent amiodarone itself. (H&E)

Masson–Fontana stain, are present in dermal macrophages. The pigment was originally thought to be lipofuscin, although melanin-containing complexes may also be present.⁹¹¹ Recently, this concept has been challenged following the finding that amiodarone itself was deposited in the skin.⁹¹³ Treatment with the Q-switched Nd:YAG laser has been successful.⁹¹⁴

Polyene antibiotics such as nystatin may also produce local lipofuscinosis.^{907,909} The mechanism responsible for the production and deposition of the lipofuscin is unknown for both these drugs.

Localized lipofuscinosis has also been reported as an incidental phenomenon.⁹¹⁵ There was no history of trauma or the application of topical agents.

Histopathology^{907,909}

Yellow-brown granules of lipofuscin are found in macrophages, which tend to accumulate around blood vessels at the junction of the papillary and reticular dermis (Fig. 14.38). The granules stain positively with the PAS, prolonged Ziehl–Neelsen, Fontana, and Sudan black methods.⁹⁰⁷

Electron microscopy

There are electron-dense, membrane-bound bodies in the cytoplasm of macrophages.^{907,909} Melanosomal maturation may be blocked in some cases.⁹¹⁶

Clofazimine

The substituted phenazine dye clofazimine is used in the treatment of leprosy, discoid lupus erythematosus, and other dermatoses. A not-uncommon side effect is the development of cutaneous and conjunctival pigmentation that has a reddish blue hue.^{812,917} Although light microscopy of routine H&E-stained sections fails to show the pigment, birefringent red clofazimine crystals can be seen in fresh frozen sections.⁹¹⁷ These deposits, which are concentrated around larger vessels in the dermis, are vivid red on fluorescence microscopy.⁹¹⁷

Differential diagnosis

Minocycline pigmentation can be confused with postinflammatory hyperpigmentation due to melanin, hemosiderin deposition in inflam-

matory or hemorrhagic processes (including areas of trauma with scar formation), and other drug-induced pigmenting conditions. The pigment does not closely resemble the yellow-brown, refractile granules due to amiodarone or the red deposits seen on fluorescence microscopy due to clofazimine. Chlorpromazine and other phenothiazines produce slate-gray pigmentation in sun-exposed areas. The dermal pigment deposits related to these agents can resemble melanin but may also have a golden, refractile quality, possibly representing the drug or a metabolite thereof. Melanin stains are positive but, unlike minocycline pigmentation of the type I variety, iron stains are negative. The pretibial slate-gray pigment seen with antimalarial therapy can stain for iron, melanin, or both and therefore could be indistinguishable from minocycline deposition in the absence of a clinical history or more sophisticated laboratory studies. The microscopic features of amiodarone and clofazimine pigmentation could be confused with one another or possibly with similar changes due to other drug metabolites. Background lesional changes submitted for microscopic study would also be important; thus, a lesion of lepromatous leprosy or discoid lupus erythematosus containing these types of pigments would suggest clofazimine therapy. There may be a role for ceroid or lipofuscin in both of these conditions. However, the red deposits due to clofazimine, seen with fluorescence microscopy and in fresh frozen sections, appear to be characteristic, and laboratory methods such as energy dispersive X-ray microanalysis and high-performance liquid chromatography could be used to identify amiodarone in tissue.

Omeprazole

Omeprazole, a potent inhibitor of gastric acid secretion, has been associated with cutaneous pigmentation, mimicking ashy dermatosis.⁹¹⁸ The pigmentation had cleared 12 months after cessation of the drug. A biopsy revealed a normal epidermis and numerous macrophages containing golden-brown granules, mainly located around blood vessels in the upper dermis. The granules stained positively with the Masson–Fontana stain but were negative for iron. Sulfur-containing material, representing the drug and/or drug–melanin complexes, was found in the cytoplasm of the macrophages.⁹¹⁸

Chemotherapeutic agents

Pigmentation of the skin may follow the prolonged use of several antineoplastic chemotherapeutic agents, including busulfan, bleomycin, doxorubicin, daunorubicin,^{919,920} fluorouracil,⁹²¹ cisplatin,^{922,923} and cyclophosphamide, and the topical application of mechlorethamine (chlormethine, mustine) and carmustine (BCNU).^{784,924} That following the use of bleomycin takes the form of ‘flagellate streaks’.^{925–930} Localization in striae distensae, areas of pressure, and in supravascular skin following venous infusions has been reported.^{931–935} Cisplatin has produced periungual hyperpigmentation.⁹²³ The pigmentation appears to result from increased melanin in the basal layer of the skin and in macrophages in the upper dermis. In the case of daunorubicin hyperpigmentation, complete disappearance has been reported 8 weeks after cessation of the therapy.⁹²⁰

CUTANEOUS IMPLANTS

Throughout the years, various agents have been injected or surgically implanted into the dermis and subcutaneous tissue as a cosmetic procedure to correct defects and scars and to augment tissues.⁹³⁶ Paraffin was one such substance, although its complication, ‘paraffinoma’ (see p. 549), is rarely seen these days.^{850,937–942} Squamous cell carcinoma is a rare complication of a paraffinoma.⁹⁴³ Bovine collagen and silicone are the agents used most frequently for these purposes. Other substances, such as gelatin matrix, polymethacrylates and acrylic

hydrogels such as Artecoll® and Dermalive®, and polyvinylpyrrolidone-silicone suspensions such as Bioplastique®, polyalkylimide fillers such as Bio-Alkamid®,⁹⁴⁴ and stabilized hyaluronic acid have been introduced recently, and it can be expected that others will be marketed in the future.^{850,936,945-947} Adverse reactions to these substances in their current form are uncommon, but granulomatous inflammation has been reported even to hyaluronic acid products.^{945,946,948-950} The various adverse cutaneous reactions to these soft tissue fillers were published in 2008.⁹⁵¹ A favorable effect of the injection of cross-linked hyaluronic acid is its stimulation of collagen synthesis, partially restoring dermal matrix components that are lost in photodamaged skin.⁹⁵² The hemostatic agent Gelfoam® is fully absorbed in 4–6 weeks, but if biopsies are done prior to this period, the characteristic collapsed net-like or honeycombed deposits will be seen.⁸⁵⁰ The material is basophilic. An excellent review of dermal filler materials and botulinum toxin was published in 2001.⁹⁵³

Hydroxyethyl starch, a key component in many colloid volume expanders used in the treatment of hypovolemic shock and otological disease, commonly produces pruritus.⁹⁵⁴ Histopathology reveals multiple cytoplasmic vacuoles in dermal macrophages, endothelial cells, and perineural cells.⁹⁵⁴

Suture material, another implant, produces a fairly stereotyped reaction with macrophages, foreign body giant cells, and some lymphocytes. In the case of absorbable sutures, collections of macrophages with brown, foamy cytoplasm often remain after absorption is complete.⁹⁵⁵ The morphological appearances of various suture materials in tissue sections were reviewed some time ago.⁹⁵⁵ A brief account of the reactions to silicone and to bovine collagen follows.

SILICONE IMPLANTS

The term *silicone* is used to designate certain polymeric organosilicon compounds that may be in liquid, gel, or solid form.^{936,953} A liquid form, dimethicone (dimethylpolysiloxane), is used to augment soft tissues. Little reaction is produced if only small amounts (<1 ml at each treatment session) are used;⁹³⁶ severe reactions with granulomas and ulceration have been reported.^{956,957} In an attempt to reduce the side effects that result from the use of large amounts of the liquid or gel forms, ‘bag-gel’ implants were introduced for augmentation of the breasts.⁹⁵⁸ Leakage of silicone can occasionally occur following trauma to the site of implantation, producing a local reaction; uncommonly, the silicone gel can migrate to distant sites, where it may result in induration or a discharging wound.⁹⁵⁹⁻⁹⁶² A lupus miliaris-like reaction on the face has been reported in a patient with silicone breast implants.⁹⁶³ Ulceration has also been recorded overlying areas of subcutaneous injection of liquid silicone.⁹⁶⁴ Silicone has also been used to construct auricular prostheses.⁹⁶⁵

Controversy surrounds the development of systemic manifestations, such as scleroderma, in patients who have received silicone implants (see p. 360). Some of these cases have been the subject of litigation.

Histopathology⁹⁶⁶

Silicones can produce a range of histological reactions, depending mainly on the form of the silicone (liquid, gel, or solid elastomer type) and the amount in the tissues.⁹⁵⁸ Liquid silicone results in round to oval vacuoles of varying size surrounded usually by histiocytes, some with foamy cytoplasm (Fig. 14.39). A few multinucleate giant cells may be present.⁹⁶⁷ Small amounts of the gel form may remain in tissue sections after processing, but the liquid forms are usually removed during paraffin processing, leading to the appearance of empty vacuoles.⁹⁵⁸ A variable fibroblastic response ensues.⁹³⁶ Artecoll® and Dermalive®, two injectable esthetic microimplants, can also produce a granulomatous reaction.⁹⁴⁵

Figure 14.39 Silicone deposits with characteristic vacuoles of varying size surrounded by macrophages and foreign body giant cells. (H&E)

The reaction to silicone elastomer (silicone rubber), as used in joint prostheses, is strikingly different from that to liquid and gel forms of silicone and takes the form of foreign body granulomas.⁹⁵⁸ The implant is sometimes extruded.⁹⁶⁸

Although earlier reports suggested that silicone is doubly refractile when examined with polarized light,⁹⁶⁹ it is now thought that this property results from adulteration of the silicone with other material.⁹⁵⁸ Talc deposition is sometimes seen with polarized light in these cases.⁹⁷⁰ It is possibly introduced at the time of the implant surgery.

COLLAGEN IMPLANTS

The injection of bovine collagen (Zyderm®) is a relatively safe procedure used to correct defects caused by acne scars, trauma, and aging.^{936,971} Adverse reactions in the form of erythema, urticaria, abscess formation, and induration of the injection site are relatively uncommon.^{971,972} Granulomatous reactions are rare (see later).^{973,974} There is a theoretical risk of prion transmission when materials of bovine origin are used. No such complication has yet been reported.⁹⁷⁵

The mechanism of action of the implant appears to be to stimulate the deposition of new collagen by fibroblasts, which are increased in the vicinity of the implant.

Bovine collagen matrix, another bovine collagen product, is used to promote hemostasis in surgical wounds. It promotes the migration and attachment of stromal and epithelial cells, thereby accelerating wound healing.⁹⁷⁶ Other implant materials are constantly being evaluated.⁹⁷⁷

Histopathology^{936,978-981}

The bovine collagen commercially available as Zyderm® is composed mainly of type I collagen of relatively small fiber diameter. It can be recognized in tissues for several weeks after its injection as finely fibrillar material between the larger bundles of native collagen. In contrast to native collagen, which is birefringent under polarized light and which stains green with Masson's trichrome stain, bovine collagen fails to refract polarized light, stains a pale gray-violet color with Masson's trichrome stain, and is only lightly eosinophilic in H&E preparations.⁹⁷⁸ Apparently, bovine collagen is absorbed because it can no longer be detected by light microscopy or immunofluorescence techniques after several months.⁹⁷⁹

Following injection of the material, a mild lymphocytic and histiocytic infiltrate is found around blood vessels in the vicinity. This is

Figure 14.40 Hyaluronic acid filler producing a granulomatous reaction. (H&E with Alcian blue inset)

followed by a slight increase in the numbers of fibroblasts and the subsequent deposition of native collagen. Calcification, which is not uncommon at the site of injection of bovine collagen into animals, has not been recorded in humans. Rare reactions include the formation of foreign body granulomas^{978,980} and abscesses⁹⁷² or of necrobiotic granulomas resembling granuloma annulare.⁹⁷³

Granulomatous reactions may also follow the use of hyaluronic acid fillers used for soft tissue augmentation (**Fig. 14.40**).

MISCELLANEOUS DEPOSITS

OXALATE CRYSTALS

Oxalate crystals can be found in the skin in some cases of primary oxalosis, a genetically transmitted disorder of oxalate metabolism characterized by hyperoxaluria, nephrolithiasis, nephrocalcinosis, and renal failure at an early age.⁹⁸²⁻⁹⁸⁴ There are two main types of primary hyperoxaluria: type I (OMIM 259900), in which there is a deficiency of the hepatic enzyme alanine-glyoxylate aminotransferase encoded by a gene at 2q36-q37; and type II (OMIM 260000), which has a deficiency of D-glycerate dehydrogenase, the gene for which maps to 9cen.⁹⁸⁵ Cutaneous deposits are unusual in secondary oxalosis, which is seen most often in patients with chronic renal failure on long-term hemodialysis.⁹⁸³ Such patients usually present with miliary deposits in the fingers, particularly on the palmar surface. A patient with multiple subcutaneous nodules and one with dermal plaques on the thigh have been reported.^{986,987} Vascular deposition of oxalate crystals in either the primary or the secondary form can produce livedo reticularis⁹⁸⁸⁻⁹⁹⁰ or cutaneous necrosis.^{991,992} These lesions may resemble calciphylaxis.⁹⁸⁵

Histopathology^{982,983,986}

Oxalate crystals, which are light yellow to brown in sections stained with H&E, are birefringent (**Fig. 14.41**). They are rhomboid in shape. They are deposited in the dermis and, rarely, as large nodular deposits in the subcutis. There may be a mild inflammatory reaction with some foreign body giant cells.

Figure 14.41 Cutaneous oxalosis. (A) Yellowish, rhomboid-shaped oxalate crystals are present in the subcutis. (H&E) (B) These crystals are birefringent when examined under polarized light.

Because the crystals usually contain calcium salts, they can be stained by the von Kossa method.⁹⁸³

In cases with livedo reticularis or cutaneous necrosis, oxalate crystals may be found in blood vessels in the subcutis.^{988,991}

Differential diagnosis

Oxalate crystals have a distinctive appearance and are relatively diagnostic. The urate crystals of gout may be somewhat similar but only when tissues are alcohol-fixed; with formalin fixation, urates have an amorphous, gray appearance, unlike oxalate crystals subjected to similar fixation. Monosodium urate crystals would not be expected to stain with von Kossa or alizarin red methods, except when secondary calcification has occurred (e.g., in older lesions). Oxalate crystals are different from other types of calcium deposits, which are distinctly dark blue in routinely stained sections, do not have a crystalline quality, and are not birefringent. In contrast to calcium phosphate and calcium carbonate, which stain with alizarin red at pH 7.0 and 4.2, oxalate crystals stain with this method at pH 7.0 but not 4.2.

FIBERGLASS

Fiberglass dermatitis is rarely seen these days. Fiberglass can be identified in the stratum corneum and sometimes in the dermis after contact with this agent.⁹⁹³

MYOSPHERULOSIS

Myospherulosis refers to the histopathological changes of ‘sac-like structures with endobodies’.^{994,995} It is an incidental finding. In some instances, myospherulosis has followed the topical application of lanolin and petrolatum. The spherules are derived from erythrocytes altered by foreign lipids and human fat.⁹⁹⁴ They are quite different from **collagenous spherulosis**, which are round eosinophilic staining globular deposits containing collagen, usually found in benign tumors.⁹⁹⁶

POLYVINYLPYRROLIDONE STORAGE DISEASE

Polyvinylpyrrolidone (PVP) was originally developed as a plasma expander but is currently widely used in skin care products, fruit juices, and as a retarding agent in some drugs. It has also been injected as a ‘tonic’. Larger polymers of PVP are permanently stored in macrophages, leading to so-called PVP storage disease.⁹⁹⁷ On biopsy, blue-gray vacuolated histiocytes are found in a perivascular location. The cells are positive for mucicarmine, colloidal iron, and Congo red stains but negative for PAS and Alcian blue stains.^{850,997}

Pityriasis folliculorum	500				

INTRODUCTION

This chapter covers the nontumorous disorders of the cutaneous appendages, the great majority of which are inflammatory diseases of the pilosebaceous apparatus. Inflammation of the apocrine and eccrine glands is quite uncommon by comparison. Hamartomas and some related congenital malformations are included with the appendageal tumors in Chapter 33 (pp. 933–935).

The following categories of appendageal diseases are considered in this chapter:

- Inflammatory diseases of the pilosebaceous apparatus
- Hair shaft abnormalities
- Alopecias
- Miscellaneous disorders.

Before considering these diseases, a brief account is given of the normal hair follicle. Because the changes that occur during the hair cycle are relevant to the alopecias, this aspect is discussed on page 481.

The normal hair follicle

Hair follicles are derived from the fetal epidermis as a downward-projecting epithelial bud, which is guided in its subsequent development by an accumulation of mesenchymal cells in the underlying dermis – the dermal papilla.¹ This process is under the control of various substances, one of which is the mesenchymal cell membrane protein known as epimorphin.²

Hair follicles are found in a variably dense population throughout the body, except for palmar–plantar skin. The follicle and its attached sebaceous gland and arrector pili muscle form a structural unit. In some parts of the body (axilla and genitocrural region), an apocrine gland is connected to the upper part of the sebaceous duct. Hair follicles produce a hair shaft, which arises from the deep portion of the follicle. Two distinct types of hair shaft are recognized: *terminal hair*, a heavily pigmented, thick shaft arising from a terminal hair follicle, which projects into the deep dermis and even into the subcutis; and *vellus hair*, a short, fine, lightly pigmented shaft that arises from a vellus hair follicle; it only extends into the upper reticular dermis. Both types of hair follicle go through a life cycle (see p. 481), but the length of the anagen phase is much shorter in vellus hair follicles.³

The hair follicle is divided into four anatomical regions – the infundibulum, the isthmus, the suprabulbar zone, and the hair bulb. The *infundibulum* extends from the skin surface to the point of entry of the sebaceous duct. Its lining cells show epidermal keratinization.

Below this is the *isthmus*, the short portion between the entry of the sebaceous duct and the attachment of the arrector pili muscle. This region contains two important structures – the bulge region and the follicular trochanter.⁴ The bulge region, which contains follicular stem cells and stains with CK19, CK15, and CD200, is a region of the outer root sheath at the point of insertion of the arrector pili muscle. Another bulge in the outer root sheath in this same region has been called the follicular trochanter. Little is known of its function.⁴ Some follicular stem cells are present in plucked hair, presumably from this region.⁵ Between the isthmus and the hair bulb is the *suprabulbar region*. The *bulb* is the expanded lower end of the follicle that includes the *dermal papilla*; it is surrounded on its top and sides by the *hair matrix*, the part of the bulb that is the actively growing portion of the hair shaft.

The terminal hair shaft is composed of three layers – the medulla, the cortex, and the inner root sheath. The *medulla* forms the central core of the hair shaft. It is not present in all human hairs, although it is an important structure of some animal hairs, such as wool.³ The size and form of the medulla, at least in scalp hair, is regulated by the stage of the hair cycle and by the cross-sectional size of the hair shaft.⁶ The *cortex* constitutes the bulk of the hair. It is composed of densely packed keratins, both epithelial keratins and keratins unique to ‘hard’ structures such as nails and hairs. There are 17 hair keratins. Like epithelial keratins, they are grouped into type I (acidic) and type II (neutral-basic) hair keratins. There are 11 type I hair keratins and 6 type II hair keratins.⁷ Under the new consensus nomenclature for mammalian keratins, there has been a change to the names of some of the keratins and to the gene designations.⁸ Gene names are preceded by *KRT*. The type I hair keratins have been designated K31–40 (there is a 33a and 33b), whereas the type II hair keratins have been designated K81–86.⁸ Because all papers in the dermatological literature referred to in this chapter used the old Moll system, it is followed here, although gene nomenclature has largely been updated.

The hair cortex is covered by a single row of overlapping cells, the *shaft cuticle*. External to the shaft cuticle are the three layers forming the *inner (internal) root sheath* – an inner *sheath cuticle* (which intermeshes with the shaft cuticle), *Huxley’s layer*, and an outer *Henle’s layer* (which keratinizes first). The three layers blend together with keratinization and are no longer distinct by the mid-follicle. Keratinization occurs through the formation of trichohyaline granules. Outside the inner root sheath is the *outer (external) root sheath*. It is composed of clear cells, rich in glycogen. It is only one cell thick at the level of the bulb; it is thickest at the isthmus, where it starts to keratinize, forming a narrow zone of trichilemmal keratinization. The single-cell inner layer of the outer root sheath undergoes specialized keratinization mediated by apoptosis.⁹ Above the isthmus, the cells

assume epidermal characteristics and line the infundibulum. Enclosing the hair follicle is a *vitreous* ('glassy') layer, which is PAS positive. It becomes thickened and wrinkled during catagen. Beyond this is the *fibrous root sheath*, which is continuous below with the follicular papilla; it blends above with the collagen of the papillary dermis. CD10 is strongly expressed in the perifollicular dermal sheath.¹⁰

The adult hair follicle contains the following keratins: the basal layer keratinocytes of the infundibulum express K5/6 and -14, whereas those in the suprabasal layer show K1, -4, -10, and -14, similar to adult epidermis. The keratinocytes of the isthmus show K5/6, -14, -17, and -19. The cells of the inner root sheath stain for K4 and K18. All stain for involucrin, including the matrical cells, which stain for nothing else.¹¹ These keratin designations have not been updated using the 2006 consensus nomenclature for mammalian keratins.⁸

The arrector pili muscle attaches to the pilosebaceous apparatus, via elastic tendons, at the bulge area. Some muscle fibers can be found admixed with the connective tissue sheath encircling the follicle. The anchor between the distal arrector pili and the extracellular matrix includes both $\alpha_5\beta_1$ integrin and fibronectin.^{12,13}

Attention has turned recently to the hair follicle immune system and its possible role in the causation of alopecia areata and the folliculitides that are a common problem in immunocompromised persons. The *distal* part of the human hair follicle appears to represent a specialized area of the skin immune system with interacting intraepithelial T cells and Langerhans cells. The sharply reduced numbers of T cells and Langerhans cells, and the virtual absence of major histocompatibility complex (MHC) class I expression, suggest that the anagen *proximal* hair follicle constitutes an area of immune privilege within the hair follicle immune system. Its collapse may be crucial to the pathogenesis of alopecia areata.¹⁴

INFLAMMATORY DISEASES OF THE PILOSEBACEOUS APPARATUS

Inflammatory diseases of the pilosebaceous apparatus are a common problem in dermatological practice, although it is unusual for biopsies to be taken in many of the entities included in this category. It often assists in arriving at a specific diagnosis if the various inflammatory diseases are subdivided into six categories, although it should be recognized at the outset that this subdivision is somewhat arbitrary. These categories are as follows:

- Acneiform lesions
- Superficial folliculitides
- Deep infectious folliculitides
- Deep scarring folliculitides
- Follicular occlusion triad
- Miscellaneous folliculitides.

Acneiform lesions combine inflammation of the pilosebaceous apparatus with the presence of comedones and often scarring as well. Comedones are dilated and plugged hair follicles that may have a small infundibular orifice (closed comedo) or a wide patulous opening (open comedo). Comedones are not confined to acne, being found in senile skin and certain other circumstances (see later).

The other categories in this section are all folliculitides. The term *folliculitis* refers to the presence of inflammatory cells within the wall and lumen of a hair follicle, whereas *perifolliculitis* denotes their presence in the perifollicular connective tissue, sometimes extending into the adjacent reticular dermis. Folliculitis and perifolliculitis are often found together because an inflammatory process in the follicle spills over into the adjacent connective tissue. If the inflammatory process is severe enough, destruction of the hair follicle will ensue. Scarring may also result if the inflammatory process is severe and/or persistent.

Five major categories of folliculitis, other than acneiform lesions, can be defined although, as previously mentioned, this subdivision is somewhat arbitrary. They are considered after the acneiform lesions are discussed.

ACNEIFORM LESIONS

Acneiform lesions are characterized by the presence of comedones, as well as inflammation of the hair follicle. The inflammatory process frequently extends into the adjacent dermis with the formation of pustules, draining sinuses, and subsequent scarring. The most important entity in this group is acne vulgaris.

ACNE VULGARIS

Acne vulgaris, an inflammatory disease of sebaceous follicles, is a common disorder that affects a large proportion of the teenage population.¹⁵⁻¹⁹ Acne vulgaris also affects people with skin of color.^{20,21} The incidence in a survey of Asian teenagers in Singapore was 88%.²² The incidence is low in non-Westernized populations.²³ It is usually a mild affliction that improves spontaneously after adolescence.²⁴ In a small proportion, it produces considerable disfigurement. Severity can impact on the quality of life of the affected individual.²⁵⁻²⁹ Acne can also be found in some neonates, infants, and adults.³⁰⁻³⁴ Infantile acne may be the initial sign of an adrenocortical tumor.³⁵ Infantile acne has a male predominance.³⁶ It may result in considerable scarring.³⁷ Late-onset acne appears to be a special group in which endogenous factors play a major role.³⁸ A high proportion of female acne is of late onset.^{39,40}

In a study published in 2006, but based on 2004 data, which was a joint project of the American Academy of Dermatology Association and the Society for Investigative Dermatology, acne was the second most costly skin disease after skin ulcers and wounds, accounting for \$2.5 billion annually in direct medical costs.⁴¹ Of this amount, \$1.74 billion was expended on prescription drugs, and this figure does not include specialty pharmaceuticals, which are often used in the treatment of acne. Incidentally, the prevalence was estimated to be 50.2 million persons.⁴¹

Acne is a polymorphic disorder with such diverse lesions as comedones, papules, pustules, cysts, sinuses, and scars.¹⁵ Scarring can be minimized by early effective treatment.^{42,43} An attempt has been made to classify the scars into several subtypes.⁴⁴ The comedones may take the form of tiny white papules known as 'whiteheads' (closed comedones) or small papules with a central core, the surface of which is black. These lesions are known as 'blackheads' (open comedones). Comedones are not confined to acne, being found in senile skin,⁴⁵ in a rare congenital form,⁴⁶ in nevus comedonicus, and following exposure to certain chemicals such as coal tar.⁴⁷ Only a few inflammatory lesions are present at any one time in mild acne, although comedones may be present and dormant for years.⁴⁸ A study has confirmed the comedonal origin of the majority of inflammatory acne lesions.⁴⁹ However, quite a few cases (28%) appear to arise from normal skin, although some microcomedones may be difficult to visualize.⁴⁹

Acne affects the face and, less frequently, the upper part of the trunk. These are sites of maximum density of sebaceous follicles.¹⁶ In one report, acne presented in a zosteriform distribution ('acne nevus').⁵⁰ In another, the acneiform rash was localized to the site of previous herpes zoster infection.⁵¹ Acne is uncommon in the scalp, suggesting that terminal follicles may have a protective function.⁵²

Etiology and pathogenesis

Acne vulgaris is of multifactorial origin with both intrinsic and extrinsic factors contributing to the final outcome.⁵³⁻⁵⁷ There are four principal pathogenetic events: abnormal follicular keratinization with retention

of keratinous material in the follicle, increased sebum production, the presence of the gram-positive anaerobic diphtheroid *Propionibacterium acnes*, and inflammation.^{16,58,59} These various factors are, in part, interrelated.

The initial event is abnormal keratinization of the infundibular portion of sebaceous follicles, leading to the impaction of adherent horny lamellae within the follicle.^{60,61} The cause of this retention hyperkeratosis is unknown, although both the formation of free fatty acids and the follicular deficiency of the fatty acid linoleic acid⁶² have been implicated at different times. Impacted follicles, which are the precursors of comedones and inflammatory lesions, are not detectable clinically.⁶⁰ They are termed 'microcomedones'.⁶³ With the recent complete mapping of the *P. acnes* genome, there is now a better understanding of the causes of the microcomedone. *Propionibacterium acnes* biofilm produces a biological glue that holds corneocytes together to form the keratin plug, which leads to the infundibular obstruction.⁶⁴ Biofilms are an important defense mechanism of bacteria. Microorganisms within biofilms are 50–500 times more resistant to antimicrobial therapies compared to free-floating (planktonic) bacteria.⁶⁴ Isotretinoin and benzoyl peroxide may alter the vitality of the *P. acnes* biofilm.⁶⁵ The microcomedone may not be the central cause of acne but merely a reflection of the action of *P. acnes* secreting substances into the sebum as they try to set up their biofilm.⁶⁴

The role of sebum is poorly understood.⁶⁶ Acne patients have increased sebum secretion by the sebaceous follicles.⁶² Sebum production is known to be under the influence of androgens,^{67,68} which are increased in some patients, particularly females, with acne.^{69–74} Dehydroepiandrosterone sulfate, the major adrenal androgen, is significantly higher in girls and adult women with acne than in age-matched controls.^{30,75,76} Insulin-like growth factor-1 (IGF-1) is also increased in adult women with acne.⁷⁶ Androgens also play a role in prepubertal acne in males.^{77,78} There are elevated levels of 17-hydroxyprogesterone in male patients with acne.⁷⁹ Of interest is the finding that some women with acne have polycystic ovaries.^{80,81} Premenstrual acne flares may occur.^{82–84} Furthermore, the injection of sebum into the skin produces inflammatory lesions that mimic those of acne.⁸⁵ The onset of sebum secretion and expansion of the propionibacterial skin flora occur earlier in children who develop acne than in children who do not.⁸⁶ Despite these findings, a recent report found no correlation between levels of sebum secretion and the number of acne lesions.⁸⁷

Propionibacterium acnes is the bacterial species most consistently isolated from lesions of acne,⁸⁸ although it is present in only 70% of early inflammatory lesions.⁸⁹ Bacteria are not essential for the formation of comedones.⁹⁰ *Propionibacterium acnes* produces several factors, other than its biofilm, that may be of pathogenetic importance,^{91–94} including lipases and proteases, chemotactic factors, and heat shock proteins.⁹⁵ *Propionibacterium acnes* can, in some way, activate the complement system, and it may stimulate the release of hydrolases from neutrophils.⁹² These may in turn damage the follicular wall, leading to the liberation of the contents of the follicle into the dermis and the consequent inflammatory reaction. *Propionibacterium acnes* also has T-cell mitogenic activity.⁹⁶ It also triggers cytokine responses in acne by activation of toll-like receptor 2 (TLR2).⁹⁷ Toll-like receptors may also result in the accumulation of pus in the acne pustule.⁶⁴ The resolution of acne lesions may involve the regulation of CD4⁺ T-cell responses to *P. acnes*.⁹⁵ Other studies suggest that an overly vigorous immune response to *P. acnes* may be the fundamental problem in patients with inflammatory acne.^{98,99} The microflora of adolescent, persistent, and late-onset acne is the same.¹⁰⁰ Antibiotic-resistant strains of *P. acnes* are present in some cases of recalcitrant acne vulgaris.^{101–104} Phototherapy has been used to treat some of these antibiotic-resistant cases.¹⁰⁵

Many external factors may influence the course of acne vulgaris.¹⁰⁶ These include drugs (halides, isoniazid, various hormones, barbiturates, lithium, etretinate, topical tacrolimus,¹⁰⁷ infliximab,^{108,109} imatinib,¹¹⁰

epidermal growth factor receptor inhibitors^{111,112} such as erlotinib,^{113,114} cetuximab,¹¹⁵ and gefitinib,¹¹⁶ anabolic steroids,¹¹⁷ sirolimus,¹¹⁸ amineptine,^{119,120} the recreational drug Ecstasy,¹²¹ and phenytoin (diphenylhydantoin)), cosmetics, soaps and shampoos, tight-fitting masks,¹²² industrial chemicals, oils and tar,¹²³ smoking,^{124–126} ultraviolet light, radiation therapy,¹²⁷ infections such as infectious mononucleosis,¹²⁸ and friction or trauma.^{129,130} The rash associated with the epidermal growth factor receptor inhibitors is sometimes folliculitis^{131,132} or rosacea-like in its appearance.^{133,134} The complications of these inhibitors have been characterized by the acronym PRIDE (papulopustules and/or paronychia, regulatory abnormalities of hair growth, itching, and dryness due to epidermal growth factor receptor inhibitors). Acne has also developed as an immune reconstitution syndrome in a patient with AIDS after initiation of antiretroviral (HAART) therapy.¹³⁵

It has been suggested that diets with a low glycemic index are less likely to result in acne,²³ but this has been questioned.^{136,137} No mention is made these days of the adverse effects of various foods in provoking acne, although occasional patients insist that a certain food exacerbates their disease.^{136,138} A study of milk consumption and acne in teenage boys found a positive association between intake of skim milk and acne.¹³⁹ An associated commentary urged caution in accepting the results.¹⁴⁰

Acneiform lesions are seen in **Apert's syndrome** (acrocephalosyndactyly; OMIM 101200).^{141,142} Its manifestations include craniosynostosis, severe syndactyly of the hands and feet, and dysmorphic facial features. The prevalence in the United States has been estimated to be 15.5 cases per 1 million live births.¹⁴³ It is due to a mutation in the fibroblast growth factor receptor 2 (*FGFR2*) gene at 10q26.¹⁴⁴ Somatic mutations in *FGFR2* can produce segmental acne (**acneiform nevus**).¹⁴⁵ Oral isotretinoin has been used to treat the acne associated with Apert's syndrome.¹⁴⁶

Acneiform lesions are also seen in pyoderma faciale, although in this condition there are cysts and draining sinuses but no comedones.¹⁴⁷ An acneiform eruption may complicate the use of topical and systemic corticosteroid therapy (**steroid acne**).^{148,149} There is some suggestion that steroid acne is exacerbated or precipitated in some way by the presence of *Malassezia* sp.¹⁵⁰ Another form of acne is **aquagenic acne**, which occurs in some swimmers. It is probably of multifactorial origin, with chlorine being only one of many contributing factors.¹⁵¹

Finally, **neonatal cephalic pustulosis**, said to be present in approximately 3% of neonates, is clinically similar to neonatal acne. It may be triggered by the yeast *Malassezia sympodialis*.¹⁵² A purported case of infantile acne due to *Malassezia* sp. has been reported.¹⁵³

The numerous treatments for acne vulgaris can be divided into topical, systemic, and alternative therapies. Topical therapies have included adapalene, retinoids, benzoyl peroxide, erythromycin or clindamycin, and salicylic acid. Among the systemic therapies are doxycycline and minocycline, tetracycline, erythromycin, trimethoprim-sulfamethoxazole, cephalixin, isotretinoin, estrogen-containing oral contraceptives, and the antiandrogens spironolactone and cyproterone. Alternative modes of treatment include photodynamic therapy, chemical peels, comedone removal, herbal agents, hypnosis/biofeedback, and lasers and/or surgery.

Histopathology^{15,154}

The three major components of acne vulgaris are comedones, inflammatory lesions, and scars. A **comedo** is an impaction of horny cells in the lumen of a sebaceous follicle.^{15,155} Preceding this is the microcomedo, a clinically invisible lesion in which there is only minimal distension of the infundibular canal of a sebaceous follicle, accompanied by increased retention of horny cells and a prominent underlying granular layer.^{59,60,156} There are two types of comedo: a closed comedo ('whitehead'), which has only a small orifice, and an open comedo ('blackhead'), which in contrast has a wide patulous orifice.¹⁵⁴

Both consist of a cyst-like cavity filled with a compact mass of keratinous material and numerous bacteria.¹⁵⁴ In the closed comedo, there are 1 or 2 hairs trapped in the lumen and atrophic sebaceous acini, whereas in the open comedo there are up to 10–15 hairs in the lumen and the sebaceous acini are atrophic or absent.^{15,154} The epithelial lining of comedones is usually thin.

The source of the pigmentation in open comedones ('blackheads') is disputed. It has been attributed to the presence of active melanocytes in the uppermost follicle, but a more recent study failed to confirm this.¹⁵⁷ It is now suggested that densely packed, often concentric, horny material, interspersed with sebaceous material and bacterial breakdown products, may be responsible for the observed pigmentation.¹⁵⁷

If comedones rupture, re-epithelialization may eventually occur, producing secondary comedones that may be distorted in shape as a consequence of the residual inflammation and dermal scarring.^{15,154} Epidermal cysts may also form, particularly on the neck. They differ from comedones by their often larger size and the complete absence of sebaceous acini and a pilary unit.¹⁵⁴ Comedones of all types may be dormant for a long period. At any time, they may become inflamed. Pseudoacne is the term given to inflammatory papules of the nasal cleft that on histology have keratin granulomas, probably the result of rupture of milia.¹⁵⁸

Inflammatory lesions have traditionally been attributed to the accumulation of neutrophils within microcomedones or comedones with subsequent rupture of the follicle and the formation of a pustule in the dermis. It now appears that there is an even earlier stage that involves the transmigration of lymphocytes into the wall of the follicle associated with increasing spongiosis of the follicular epithelium (Fig. 15.1).¹⁵⁶ This change has been likened to an allergic contact sensitivity reaction.¹⁵⁶ This is followed after 24–72 hours by the accumulation of neutrophils within the follicle, leading to its distension and subsequent rupture.¹⁵⁶ There may be a localized loss of the granular layer in the region of the eventual rupture, suggesting a defect in keratinization in this region. A perifollicular pustule develops following the rupture of the comedo (Fig. 15.2). Lymphocytes, plasma cells, and foreign body giant cells subsequently appear. The follicular epithelium tends to encapsulate the inflammatory mass; sometimes this is followed by the formation of draining sinuses lined by remnants of the follicular epithelium. When the inflammatory process subsides, distorted secondary comedones may result.

Figure 15.1 Acne vulgaris (early lesion). There is transmigration of lymphocytes through the spongiotic epithelium lining a microcomedone. A few neutrophils are present along the inner edge. (H&E)

Scars in acne vulgaris may take the form of localized dermal fibrosis or of hypertrophic scars, even with keloidal changes. Small atrophic pits are quite common.¹⁵⁴ A thin fibrotic dermis, devoid of appendages, is found directly beneath the epidermis-lined pit. Perifollicular fibrosis and elastolysis,¹⁵⁹ dystrophic calcification, osteoma cutis,¹⁶⁰ and localized hemosiderosis¹⁶¹ are other complications of inflammatory acne lesions. A microscopic study of acne lesions treated with a dual mode of quasi-long pulse and Q-switched 1064 nm neodymium:yttrium aluminum garnet (Nd:YAG) laser, assisted with a topically applied carbon suspension, showed reduced inflammation; decreased immunostaining intensity for interleukin-8 (IL-8), matrix metalloproteinase-9 (MMP-9), toll-like receptor-2, and nuclear factor- κ B; and significant reduction of tumor necrosis factor- α (TNF- α).¹⁶²

Electron microscopy

Comedones contain keratinized cells, sebum, organisms, and hairs.¹⁶³ Treatment with isotretinoin leads to a reduction in the quantity of this material and a loss of cohesion between the keratinized cells.¹⁶⁴ In early acne, the cells of the infundibulum contain numerous tonofilaments and desmosomes but fewer lamellar granules than usual.⁵⁹

Figure 15.2 Acne vulgaris. A perifollicular pustule is present in the dermis. It contains liberated hair shafts. (H&E)

ACNE FULMINANS

Acne fulminans is a rare, acute form of acne, found usually in young adult males.^{165,166} There is a sudden onset of painful, ulcerated, and crusted lesions accompanied by fever, musculoskeletal pain, and leukocytosis.^{165,167} Lytic lesions of bone develop in 25% of cases.^{165,168–170} A subgroup without systemic features has been reported.¹⁷¹ Acne fulminans has been reported in association with Crohn's disease,¹⁷² erythema nodosum,^{173,174} and the use of testosterone.¹⁷⁵ It has also been precipitated by the use of isotretinoin in the treatment of acne vulgaris.¹⁷⁶ Familial cases have been reported.¹⁷⁷

The etiology of this condition is unknown, although there is speculation that immune mechanisms are involved.¹⁶⁸ This is supported by the response that occurs to systemic corticosteroid therapy.^{167,178}

Acne fulminans, or another pustular dermatosis such as acne conglobata, palmoplantar pustulosis, hidradenitis suppurativa, or pustular psoriasis, may occur as the cutaneous manifestation of **SAPHO syndrome** (synovitis, acne, pustulosis, hyperostosis, and osteitis).^{179–181}

Systemic corticosteroids are the mainstay of therapy for acne fulminans. The use of adjuvant oral retinoids is controversial because their use for acne vulgaris may precipitate the condition.¹⁷⁶ Cyclosporine (ciclosporin), methotrexate, and infliximab have all been used as single adjuvants with corticosteroids.¹⁸⁰

Histopathology¹⁸²

Comedones are uncommon in acne fulminans. There are extensive inflammatory lesions in the dermis, with neutrophil predominance,¹⁸³ associated with necrosis of follicles and the overlying epidermis. Follicles distended with neutrophils are also present. Severe dermal scarring usually follows the subsidence of the inflammation.

CHLORACNE

Chloracne is an acneiform eruption caused by systemic poisoning by halogenated aromatic compounds.^{184–186} Although the brominated compounds tend to be more toxic, the term 'chloracne' stems from the chlorinated version.¹⁸⁸ Industrial exposure is the usual source of the chloracnogens, although exposure to defoliants containing dioxin was encountered in the Vietnam War.^{189–192} Cutaneous lesions may persist for long periods after the last exposure to the offending chemical.

Chloracne is distinct from other forms of acne.¹⁸⁴ It most often involves the malar crescent, the retroauricular region, and the scrotum and penis. Erythema and pigmentation of the face may also occur.¹⁸⁴ The primary lesion is the comedo, which is intermingled with small cysts.¹⁸⁴ Inflammatory lesions are sparse. Dioxins have also produced areas resembling granuloma annulare and atrophoderma vermiculatum.¹⁸⁴

Histopathology^{184,189}

There is follicular hyperkeratosis with infundibular dilatation forming bottle-shaped and columnar funnels containing keratinous debris. Comedones and keratinous cysts with an attachment to the epidermis also form.¹⁸⁹ Small infundibular cysts appear to be more common than comedones.¹⁸⁶ A characteristic feature is the absence, or marked diminution in size, of sebaceous glands (Fig. 15.3).¹⁸⁷ Small inflammatory foci may be present. Inflammation, when it occurs, tends to be a late event, associated with follicular rupture.¹⁸⁷ Abundant melanin granules impregnate the corneocytes of the infundibular plugs.¹⁸⁶

SUPERFICIAL FOLLICULITIDES

In the superficial folliculitides, the inflammatory infiltrate is found beneath the stratum corneum overlying a hair follicle and/or in the

Figure 15.3 Chloracne. Numerous comedones and keratinous cysts are identified, with adjacent mild lymphocytic inflammation. Sebaceous glands are conspicuously absent. (H&E)

follicular infundibulum. Disruption of the follicle wall may lead to inflammation of the upper dermis adjacent to the affected hair follicle.

ACUTE SUPERFICIAL FOLLICULITIS

Acute superficial folliculitis, also known as impetigo of Bockhart, is characterized by small pustules developing around follicular ostia and frequently pierced by a hair.^{193,194} *Staphylococcus aureus* has been implicated in the etiology.

Histopathology

There is a subcorneal pustule overlying the follicular infundibulum. In addition to neutrophils, there are also lymphocytes and macrophages in the infiltrate, which usually extends into the upper follicle and the surrounding dermis. A morphologically similar entity confined to the scalp and possibly related to infection with *P. acnes* has been reported as chronic nonscarring folliculitis of the scalp.¹⁹⁵

ACTINIC FOLLICULITIS

There have been several reports of a pustular folliculitis of the face and upper part of the trunk following exposure to sunlight.^{196–200} The lesions usually appear 4–6 hours after the exposure.²⁰¹ Typically, the lesions develop annually following the first sun exposure and resolve within approximately 10 days; there can be recurrences following similar exposure after a 4-week latency period.²⁰² The mechanism by which exposure to ultraviolet light results in folliculitic lesions remains to be elucidated, although the condition may be related to acne vulgaris and acne estivalis.¹⁹⁸

Histopathology

The microscopic changes are those of an acute superficial folliculitis.^{196,199} Subcorneal pustules are also present.²⁰⁰ No organisms are seen, and bacterial cultures have been negative.

ACNE NECROTICA

Acne necrotica (acne varioliformis) is a rare dermatosis of adults, consisting of crops of erythematous, follicle-based papules that become superficially necrotic, umbilicated, and crusted, with subsequent

Figure 15.4 Acne necrotica. Confluent necrosis involves the upper follicle and adjacent epidermis and papillary dermis. An adjacent follicle shows a superficial folliculitis. (H&E)

healing that produces a depressed varioliform scar.^{203–205} Only a small number of active lesions may be present at any time. They develop on the frontal hairline, forehead, and face and sometimes on the upper part of the trunk.

Acne necrotica miliaris has been regarded as a pruritic, nonscarring variant of acne necrotica in which follicular vesiculopustules develop on the scalp.²⁰³ This condition has been regarded as nothing more than neurotic excoriations superimposed on a bacterial folliculitis, an etiology that has also been proposed for acne necrotica itself.²⁰⁶

Histopathology²⁰³

Early lesions show an intense perivascular and perifollicular lymphocytic infiltrate extending to the mid dermis and associated with prominent subepidermal edema. The infiltrate also extends into the wall of the upper part of the follicle and into the epidermis, where there is associated spongiosis and death of individual keratinocytes. Later, there is confluent necrosis of the upper follicle, the epidermis, and the dermis. At this stage, neutrophils are seen in the upper follicle and the adjacent dermis. A florid superficial folliculitis and perifolliculitis are sometimes present (Fig. 15.4).

Biopsies of acne necrotica miliaris may show superficially inflamed excoriations, centered on hair follicles.²⁰⁶ It is unusual to have an intact lesion biopsied; presumably, a superficial folliculitis would be seen.

NECROTIZING FOLLICULITIS OF AIDS

A necrotizing folliculitis is a rare cutaneous manifestation of AIDS or its prodromes.²⁰⁷

Histopathology

Although the folliculitis and perifolliculitis may not be confined to the superficial follicle, this condition is classified with the superficial folliculitides because the accompanying necrosis is confined to the upper part of the follicle and the adjacent epidermis and superficial dermis, characteristically in a wedge-shaped area.²⁰⁷ There is fibrinoid necrosis of vessels at the apex of the wedge.

A spectrum of other folliculitides is also seen in HIV-infected patients, including acute folliculitis due to bacteria and/or yeasts, lymphocytic perifolliculitis, eosinophilic folliculitis, perifolliculitis with mixed inflammation, and follicular rupture with granulomatous perifolliculitis.²⁰⁸

EOSINOPHILIC (PUSTULAR) FOLLICULITIS

Eosinophilic (pustular) folliculitis is a heterogeneous group of disorders with several clinical subsets:

- The classic form, eosinophilic pustular folliculitis (Ofuji's disease)
- HIV-associated eosinophilic pustular folliculitis
- Pediatric eosinophilic pustular folliculitis
- Fungal and parasitic eosinophilic folliculitis
- A miscellaneous group.

The classic form, *eosinophilic pustular folliculitis (Ofuji's disease)*, is a rare, chronic dermatosis, first described in the Japanese^{209–211} but now reported occasionally in white and other races.^{212–217} There are recurrent, sterile, follicular papules and pustules with a tendency to form circinate plaques.^{218–220} These may show central clearing with residual hyperpigmentation. 'Seborrheic areas', such as the face, trunk, and extensor surface of the proximal part of the limbs,²²¹ are usually involved, but in 20% of cases the non-hair-bearing palms and soles may also be involved.²¹⁸ For this reason, the designations 'eosinophilic pustular dermatosis'²²² and 'sterile eosinophilic pustulosis' have been suggested as more appropriate titles. There is a male preponderance.²¹⁷ The mean age at presentation in one series was 35 years.²²³ A peripheral leukocytosis and eosinophilia are often present. Various case reports have described exacerbation by pregnancies,²²⁴ association with pathergy,²²⁵ and development of the disease in association with palmoplantar psoriasis.²²⁶

The condition reported in two brothers as 'circinate eosinophilic dermatosis' has some similarities.²²⁷

The etiology of eosinophilic pustular folliculitis is unknown. Interestingly, a similar lesion has been reported in dogs.²²⁸ Various immunological abnormalities have been reported in some patients, but this is not a constant feature.^{229,230} Circulating antibodies to basal cell cytoplasm²³¹ and also intercellular antigens have been noted.²³² Chemotactic factors have also been isolated from the skin.²³³ More recently, it has been suggested that the production of nitric oxide by eosinophils may have a pathogenetic role.²³⁴

HIV-associated (immunosuppression-associated) eosinophilic pustular folliculitis has been regarded as a subset of the pruritic papular eruption of HIV infection.^{220,235–243} It differs from the classic form (Ofuji's disease) by the severe pruritus, the absence of circinate and palmoplantar lesions, and the less frequent involvement of the face.²⁴⁴ However, in women with HIV infection, eosinophilic folliculitis may predominantly involve the face and can mimic acne excoriee.²⁴⁵ Coexisting follicular mucinosis has been reported in some patients.^{246,247} It has been suggested that HIV-associated eosinophilic folliculitis is an autoimmune disease with the sebocyte or some constituent of sebum acting as the autoantigen.²⁴⁸ Immunohistochemistry shows increased expression of IL-4 and -5, as well as eotaxin.²⁴⁹ There is evidence that the prostaglandin D(2)/prostaglandin J(2)-peroxisome proliferator-activated receptor gamma pathway induces sebocyte production of eotaxin, which may explain the prominent perifollicular eosinophilic infiltrates in this disease.²⁵⁰ In one patient, the eruption appeared to be related to the use of foscarnet therapy.²⁵¹ Although the onset of eosinophilic folliculitis may be initiated by antiretroviral therapy, eosinophilic folliculitis may respond favorably to treatment with this therapy.²⁵²

Pediatric (childhood) eosinophilic pustular folliculitis is usually confined to the scalp, although grouped aggregates of follicular pustules can occur on the face, extremities, and trunk in some patients.^{253–256} Onset can be as early as the first day of life.²⁵⁷ It is seen most frequently in white people, but Japanese cases occur.²⁵⁸ It usually has a self-limited course. This condition is no longer regarded as a variant of eosinophilic folliculitis because interfollicular inflammation is sometimes the predominant feature. Eosinophilic pustulosis appears to be an appropriate

designation for these cases. Ziemer and Böer have questioned the existence of this variant, stating that previously reported cases encompass a spectrum of eosinophil-rich dermatoses including scabies and other bite reactions.²⁵⁹

Fungal eosinophilic folliculitis is usually a localized disease characterized by erosive and pustular plaques.^{260,261} *Trichophyton rubrum* can produce a folliculitis that is histologically identical to eosinophilic pustular folliculitis.²⁶² Larva migrans, *Toxocara canis*, and scabies may be associated with an eosinophilic folliculitis.^{263,264} Eosinophilic folliculitis in an HIV-infected patient was apparently associated with *Demodex folliculorum* infestation, and it was successfully treated with ivermectin.²⁶⁵

The *miscellaneous group* includes patients in whom bacteria, such as *Pseudomonas*, have been isolated and patients with myeloproliferative or other hematological disorders.^{266–269} It has been reported in association with pulmonary eosinophilia²⁷⁰ and following allogeneic peripheral blood stem cell transplantation.²⁷¹ Nine HIV-negative patients with an atopic diathesis have been reported with ulcerative and/or nodular plaques mainly on the face and/or extremities, sometimes in an annular configuration. Other necrotizing variants have been reported.^{272,273} The histology was that of a necrotizing eosinophilic folliculitis. These cases appear to be the ‘eosinophilic equivalent’ of sterile neutrophilic folliculitis with perifollicular vasculopathy (see p. 472). Drugs such as allopurinol, carbamazepine, and minocycline have been associated with an eosinophilic folliculitis.^{274–276} It has also followed the use of a fentanyl-TTS patch²⁷⁷ and chemotherapy.²⁷⁸ Rarely, pemphigus vegetans may present as an eosinophilic folliculitis.²⁷⁹ A case associated with the nevoid basal cell carcinoma syndrome resolved after removal of the jaw cyst associated with the syndrome.²⁸⁰

The treatment of choice for the classic type of eosinophilic pustular folliculitis is indomethacin, but maintenance or adjuvant therapy is generally also used.^{223,272,281} Other treatments include tacrolimus, pimecrolimus,^{282–284} dapsone,²⁸⁵ isotretinoin, naproxen,²⁸⁶ metronidazole,²⁸⁷ doxycycline,²⁸⁸ sequential interferon- γ (IFN- γ), and cyclosporine.²⁸⁹ Patients with HIV-associated disease have been treated with indomethacin, narrowband UVB phototherapy,²⁹⁰ and tacrolimus.²⁹¹

Histopathology^{212,213,218,255}

The various clinical subsets of eosinophilic folliculitis have a similar histological appearance.²⁵⁵ There is eosinophilic spongiosis and pustulosis involving particularly the infundibular region of the hair follicle. The infiltrate often extends into the attached sebaceous duct and sebaceous gland (Fig. 15.5). Most follicles are preserved, but some show disruption or destruction of the wall by the inflammatory infiltrate.²¹² Follicular necrosis and folliculocentric necrotizing eosinophilic vasculitis were features of the cases reported in association with an atopic diathesis (discussed previously).²⁹² In addition to the eosinophils, there are variable numbers of neutrophils and some mononuclear cells; neutrophils are usually sparse.²⁵⁵ Using the monoclonal antibody BB1, Otsuka *et al.* found similar infiltrations of basophils in most of their cases of eosinophilic pustular folliculitis.²⁹³ There is also a moderately dense, perivascular and perifollicular inflammatory cell infiltrate composed of lymphocytes, eosinophils, mast cells, and macrophages.²⁹⁴ A PAS or silver methenamine preparation should always be examined because dermatophyte infections occasionally give a similar appearance.^{231,295}

Lesions on the palms and soles show subcorneal and intraepidermal pustules. There is a variable inflammatory infiltrate in the underlying dermis. A recently reported case showed that the intraepidermal pustules involving the palm were centered around the intraepidermal portions of eccrine ducts. Immunohistochemical staining detected dermcidin within the pustules – a peptide with antimicrobial properties secreted by the eccrine apparatus.²⁹⁶

Figure 15.5 Eosinophilic pustular folliculitis in an HIV-positive patient. (A) There is an intraluminal eosinophilic abscess with dense infiltration of the follicle, including sebaceous glands. A significant percentage of these cells are eosinophils. (B) This image shows detail of the intraluminal eosinophilic abscess. A portion of a demodex mite can also be observed. (H&E)

Differential diagnosis

Specific follicular infiltrates by eosinophils is a relatively unique histopathologic feature and should suggest one of the clinical types of eosinophilic folliculitis. The other well-known eosinophilic folliculitis occurs in erythema toxicum neonatorum, but that condition occurs during the first few days of life and presents as patchy erythema of the face, trunk, and proximal extremities and typically resolves within 1 week. Because eosinophilic folliculitis can also result from dermatophytosis parasitic disease and certain drugs, clinical history, review of medications, and special stains for organisms may be indicated in some cases. The coexistence of eosinophilic folliculitis and follicular mucinosis creates a potential diagnostic dilemma because eosinophils are commonly found in cases that otherwise present clinically and histopathologically as follicular mucinosis; in such instances, these cells are usually in the minority. However, careful evaluation may be necessary in lesions that show both changes, particularly because follicular mucinosis is now widely regarded to be a form of T-cell lymphoid

dyscrasia. Careful attention should then be paid to the lymphocytes in the dermal and perifollicular infiltrates. Eosinophils in follicular infundibula and sebaceous glands, and clustered neutrophils within infundibula, favor a diagnosis of HIV-induced follicular mucinosis;²⁴⁵ gene rearrangement studies may be necessary in select cases. In a study comparing pruritic papular eruption and eosinophilic folliculitis of HIV infection, only quantitative rather than qualitative differences were found, suggesting that these conditions may be part of a spectrum of disease. However, in the latter condition, there are more numerous mast cells and higher expression of CD15, CD4, and CD7.²⁹⁷

INFUNDIBULOFOLLICULITIS

Infundibulofolliculitis is mentioned here for completeness, although it is discussed in further detail with the spongiotic tissue reaction (see p. 110). The histopathological changes are those of follicular spongiolysis. A few neutrophils may be found in the spongiotic infundibulum or in the keratin plug that is sometimes present in the involved follicle. A variable mononuclear cell infiltrate usually surrounds the upper dermal portion of the hair follicle.^{298,299}

DEEP INFECTIOUS FOLLICULITIDES

In this group of folliculitides, the inflammatory process involves the deep portion of the hair follicle, although both superficial and deep inflammation may be present (Fig. 15.6). The etiological agents include bacteria, fungi, and viruses and are not always easily identified in routine tissue sections. A folliculitis is an uncommon presentation of secondary syphilis and of a nematode infestation.³⁰⁰

FURUNCLE

A furuncle (boil) is a deep-seated infection centered on the pilosebaceous unit.³⁰¹ Boils commonly occur at sites of friction by clothing such as the back of the neck, the buttocks, and inner aspect of the thighs. The lesion begins as a painful, follicular papule with surrounding erythema and induration.³⁰¹ The center usually becomes yellow, softens, and discharges pus. A rim of desquamation often surrounds the infected hair follicle.³⁰² Healing takes place with minimal scarring. A carbuncle is a coalescence of multiple furuncles that may lead to multiple points of drainage on the skin surface. There are often constitutional symptoms. A furuncle caused by community-acquired methicillin-resistant *Staphylococcus aureus* (MRSA) resulted in sepsis (an early manifestation of which was generalized musculoskeletal aching) and death in a recently reported case.³⁰³ An *axillary web syndrome* (a cord-like structure extending from axilla to medial arm) has been described as a consequence of an axillary furuncle. The cord is most likely the result of fibroblastic proliferation around a lymphatic vessel – a situation most often associated with axillary surgery in women with breast cancer.³⁰⁴ Furunculosis may develop in the region of a healed herpes zoster scar as a form of Wolf's isotopic response.³⁰⁵

Staphylococcus aureus is the organism most often involved.³⁰⁶

Histopathology³⁰⁷

A furuncle consists of a deep dermal abscess centered on a hair follicle. This is usually destroyed, although a residual hair shaft is sometimes present in the center of the abscess. There is often extension of the inflammatory process into the subcutis. The overlying epidermis is eventually destroyed, and the surface is covered by an inflammatory crust.

Figure 15.6 Acute folliculitis of fungal etiology involving both the superficial and deep portion of the follicle. (H&E)

PSEUDOMONAS FOLLICULITIS

Pseudomonas folliculitis is usually caused by *Pseudomonas aeruginosa*. It presents as an erythematous follicular eruption that may be maculopapular, vesicular, pustular, or polymorphous.^{308,309} It usually involves the trunk, axillae, and proximal parts of the extremities. There may be constitutional symptoms.³¹⁰ Lesions develop 8–48 hours after recreational exposure to the organism, which is found in contaminated sponges, whirlpools, and hot tubs.^{311–314} It has also been reported following depilation³¹⁵ and as a consequence of reusing rubber gloves contaminated with the organism.³¹⁶ Organisms other than *Pseudomonas* may be responsible for hot tub (spa bath) folliculitis.³¹⁷ Spontaneous clearing usually occurs within 1 week. Sporadic cases, without recreational exposure, also occur.³¹⁸

Histopathology³⁰⁸

There is an acute suppurative folliculitis that may be both superficial and deep (Fig. 15.7). If disruption of the follicular wall occurs, dermal suppuration may result. Attempts to demonstrate organisms in conventional histological preparations are usually unsuccessful.

Figure 15.7 'Hot tub' folliculitis. (A) A superficial and deep folliculitis is present. (B) Rupture has occurred into the dermis. (H&E)

OTHER BACTERIAL FOLLICULITIDES

A folliculitis caused by gram-negative bacteria may occur as a complication of prolonged antibiotic therapy in patients with acne vulgaris.³¹⁹ Most of these infections are caused by a subgroup of lactose-fermenting bacteria, resulting in superficial pustules grouped around the nose. *Pseudomonas aeruginosa* has also been implicated in this clinical setting.³²⁰ In others, deep nodular and cystic lesions occur as a result of infection by species of *Proteus*.³¹⁹ *Citrobacter diversus*, *Acinetobacter baumannii*,³²¹ *Klebsiella* sp.,³²² *Escherichia coli*, and *Enterobacter* sp. have also been implicated.^{323,324} In immunocompromised patients, organisms that are not usually pathogens, such as *Micrococcus*, have been involved.³²⁵

Bacteria, possibly complicating the application of various oils to the skin, have been implicated in a pustular eruption of the legs seen in areas of Africa and India and known as dermatitis cruris pustulosa et atrophicans.³²⁶ *Salmonella dublin* was isolated from one case of widespread folliculitis.³²⁷ There is evidence that bacterial biofilms form in the infrainfundibular portions of scalp hair follicles;

Figure 15.8 Herpes zoster-related folliculitis. This image shows extensive inflammation involving and largely destroying a follicular unit. In this particular case, characteristic herpesvirus cytopathic changes can be seen in and adjacent to the follicular ostium (arrow). (H&E)

these were found both in patients with folliculitis decalvans and in controls.³²⁸

Histopathology

Both a superficial and a deep folliculitis may be present in these bacterial folliculitides. There is variable involvement of the perifollicular dermis.

VIRAL FOLLICULITIS

The pilosebaceous follicle may be infected with herpes simplex virus type I. Vesicular or pustular lesions may not be obvious clinically.³²⁹ Recently, it has been shown that infections with varicella zoster virus (VZV) are more common as a cause of a folliculitis than herpes simplex virus.³³⁰ A granulomatous folliculitis has been reported as a manifestation of post-herpetic isotopic response.^{331,332} Herpetic folliculitis (due to herpes simplex virus) has also been found in lesions of eczema herpeticum.³³³

Histopathology

In herpes folliculitis, there is often partial or complete necrosis of the follicle with exocytosis of lymphocytes into the follicular wall and the attached sebaceous gland.³³⁰ Sometimes there is adjacent dermal necrosis. The epidermis sometimes shows the typical features of herpetic infection (Fig. 15.8). Epidermal changes are said to be uncommon in herpes zoster-related folliculitis.³³⁰ At other times, a 'bottom heavy' perivascular and interstitial dermal inflammatory cell infiltrate, which may simulate a pseudolymphoma or lymphoma, is the only clue.³³⁴ In a recent case, the atypical lymphoid infiltrate showed an angiocentric and angiodestructive component in addition to periadnexal involvement; immunostaining showed a predominance of CD3⁺ cells, with a scattering of CD20⁺ and CD56⁺ cells.³³⁵ This type of finding necessitates the cutting of multiple deeper sections in search of an involved hair follicle. The most consistent finding in herpes folliculitis is lymphocytic folliculitis and perifolliculitis.³³⁰ Inclusion bodies and multinucleate cells are not always found in the follicular epithelium. A syringitis may accompany the folliculitis.³³⁶

Viral-associated trichodysplasia

Viral-associated trichodysplasia (pilomatrix dysplasia, cyclosporine-induced folliculodystrophy,³³⁷ virus-associated trichodysplasia spinulosa^{338,339}) is a recently described follicular dystrophy of presumptive viral origin associated with immunosuppression.^{340–342} Patients present with numerous, disfiguring, papular, and spiny lesions, predominantly affecting the central face.³⁴³ Alopecia may be present elsewhere on the body.³⁴⁴ Ultrastructurally, there are intranuclear viral particles consistent with polyomavirus.³³⁸ There are anecdotal reports that topical cidofovir, an antiviral agent, has resulted in improvement in the condition.³⁴³ Oral valganciclovir has been useful in a pediatric patient.³⁴⁵

Histopathology

In viral-associated trichodysplasia (Fig. 15.9), there is dilatation and keratotic plugging of the infundibula with marked dystrophy, expansion of the inner root sheath, and an absence of hair papillae.³⁴⁵ Basophilic germinative cells transition to inner root sheath cells with enlarged, irregular, trichohyaline granules and numerous apoptotic cells. The inner root sheath cells cornify abruptly, without formation of a granular cell layer.³⁴⁵ There is bulbar distension and lack of hair shaft formation.^{338,343} Evidence of viral cytopathic effect, including vacuolated keratinocytes, pyknotic nuclei, and coarse keratohyaline, can be seen in upper perifollicular epithelium.³⁴⁵ Using an immunohistochemical stain for polyomavirus middle T antigen, there is positive

Figure 15.9 Viral-associated trichodysplasia. The patient was on immunosuppressive therapy. (H&E)

staining of inclusions within keratinocytes comprising the inner root sheath, indicating the presence of polyomavirus.³⁴⁶ Inflammation is usually mild.³⁴⁷

Electron microscopy and molecular analysis

In one study, viral particle arrays were found within extracellular material in the deep portion of a follicle but not in the abnormal inner root sheath cells.³⁴⁸ However, in another study using scanning electron microscopy, small icosahedral intracellular viral particles were found within inclusions of inner root sheath keratinocytes.³⁴⁶ DNA polymerase chain reaction (PCR) analyses have been positive for polyomavirus,^{346,348} and gene sequencing studies have demonstrated polyomavirus TSPyV,³⁴⁸ first detected by van der Meijden *et al.* in 2010.³⁴⁹ This polyomavirus is different from that involved in Merkel cell carcinoma.

DERMATOPHYTE FOLLICULITIS

Fungal elements may be seen on or within the hair shafts in certain dermatophyte infections, particularly tinea capitis. Various organisms may be involved, particularly *Trichophyton tonsurans*, *Microsporum canis*, and *M. audouinii*.³⁵⁰ Sometimes an inflamed boggy mass, known as a kerion, develops.

Histopathology

There is variable inflammation of the follicle and perifollicular dermis. If disruption of the hair follicle occurs, a few foreign body giant cells may be present. Hyphae and arthrospores may be found within the hair shaft or on the surface, depending on the nature of the infection. PAS or methenamine silver preparations are usually required in order to demonstrate the fungal elements.

Abscess formation with partial or complete destruction of hair follicles occurs in a kerion.

PITYROSPORUM FOLLICULITIS

Pityrosporum folliculitis, resulting from infection of the follicle by *Malassezia* sp. (*Pityrosporum*), is described on page 697. The small oval yeast responsible can be seen within the inflamed follicle and may be found in the adjacent dermis following rupture of the follicle.

DEEP SCARRING FOLLICULITIDES

In the deep scarring group, there is severe folliculitis involving the deep part of the follicle and often the upper part as well. Rupture of the follicle and its contents into the dermis leads to eventual scarring of variable severity. It is usually mild in folliculitis decalvans, but it is quite marked in folliculitis keloidalis nuchae. A similar picture can be seen following severe petrol burns of the skin.

FOLLICULITIS DECALVANS

Folliculitis decalvans is a chronic form of deep folliculitis that usually occurs on the scalp as oval patches of scarring alopecia at the expanding margins of which are follicular pustules.^{193,351} Any or all of the hairy areas of the body may be involved. Folliculitis barbae (lupoid sycosis) is a related condition confined to the beard area, whereas epilating folliculitis of the glabrous skin is the name used in the earlier literature for a related condition involving the legs.³⁵² An example of folliculitis decalvans of the scalp was initially interpreted as a laceration/scalp trauma at a forensics scene.³⁵³ Folliculitis decalvans has been reported in identical twins.³⁵⁴ A case has been associated with erlotinib therapy.³⁵⁵

Folliculitis decalvans usually runs a prolonged course of variable severity. The development of squamous cell carcinoma is a rare complication.³⁵⁶ The etiology is unknown, although *S. aureus* is sometimes cultured from the lesions.³⁵⁷ It appears that early lesions are characterized by an infiltration of activated T-helper cells. IL-8 and ICAM-1 may contribute to the infiltration of neutrophils.³⁵⁸

The very existence of this entity has been questioned, although the author still uses this diagnosis. Ackerman states that it is best to eschew the term,³⁵⁹ whereas Sperling believes that most cases represent a highly inflammatory form of central centrifugal cicatricial alopecia.³⁶⁰

Tufted hair folliculitis (see p. 496) has been regarded as a clinicopathological variant of folliculitis decalvans,³⁶¹ but because it can be associated with other disease processes, it is best regarded as a distinct process.³⁶²

Histopathology^{193,351}

Initially, there is a folliculitis; this is followed by disruption of the follicular wall and liberation of the contents of the follicle into the dermis (Fig. 15.10). The dermis adjacent to the destroyed follicle contains a

Figure 15.10 Folliculitis decalvans. The patient had a scarring alopecia. There is early disruption of the wall of an inflamed follicle. (H&E)

mixed inflammatory cell infiltrate. Plasma cells are sometimes present in the infiltrate, particularly in resolving lesions. Foreign body giant cells may form around the hair shafts lying free in the dermis. Variable scarring results, but this is never as severe as in folliculitis keloidalis nuchae.

FOLLICULITIS KELOIDALIS NUCHAE

Folliculitis keloidalis nuchae, also known as acne keloidalis, is a rare, idiopathic, inflammatory condition of the nape of the neck, restricted almost exclusively to adult males.^{363–366} Approximately 90% of patients are younger than age 40 years.³⁶⁷ It is a form of primary scarring alopecia of the occipital and nuchal region.³⁶⁸ It is more common in black people of African origin. There are follicular papules and pustules that enlarge, forming confluent, thickened plaques, sometimes with discharging sinuses.^{363,369} The lesions have caused secondary cutis verticis gyrata in affected persons.^{370,371} Scarring results from this chronic inflammatory process. Surgery is sometimes required to manage the condition, when treatment with topical corticosteroids/antibiotics and oral antibiotics fails.^{372,373}

The pathogenesis of this condition and the reasons for its occipital localization are not known. Postulated mechanisms include a seborrheic constitution, incurving hairs resulting from recurrent low-grade trauma (e.g., by football helmets),^{366,374} the use of antiepileptic drugs or cyclosporine,^{375,376} and an increase in mast cell numbers in the occipital region.^{377–379} Tinea capitis was the cause in one case.³⁸⁰

Histopathology^{368,364}

There is an initial folliculitis with subsequent rupture and destruction of the follicle and liberation of hair shafts into the dermis (Fig. 15.11).³⁶⁴ Usually, by the time a biopsy is taken, there is already dense dermal fibrosis with a chronic inflammatory cell infiltrate that includes numerous plasma cells. Hair shafts are present in the dermis, and these are surrounded by microabscesses and/or foreign body giant cells. Sinus tracts may lead to the surface. Sometimes there are claw-like epidermal downgrowths associated with the transepidermal elimination of hair shafts and inflammatory debris.³⁸¹ Involved follicles may show tufted hair folliculitis while intact follicles at the margins may show polytrichia.^{363,382} Keloid fibers develop within the dense fibrous tissue in some cases.³⁶³

FOLLICULAR OCCLUSION TRIAD

The follicular occlusion triad refers to hidradenitis suppurativa, dissecting cellulitis of the scalp, and acne conglobata. These three conditions constitute a form of deep scarring folliculitis: they are grouped together on the basis of their presumed common pathogenesis of poral occlusion followed by bacterial infection.³⁸³ The presence of draining sinuses is a further characteristic feature of this group. Rarely, cases occur with exophytic abscesses and fibrosis in unusual sites, such as the chin, that have all the features of the follicular occlusion triad.³⁸⁴ It has been suggested that pilonidal sinus is a related entity. These follicular occlusion disorders may coexist.³⁸⁵

ACNE INVERSA (HIDRADENITIS SUPPURATIVA)

Acne inversa (hidradenitis suppurativa) is a chronic, relapsing, inflammatory disorder involving the terminal hairs of one or more apocrine gland-bearing areas, which include the axillae, groins, pubic region, and perineum.^{386–392} The author has responded to pleas to abandon the term hidradenitis suppurativa because it is a misnomer in favor of acne inversa,³⁹³ which may be another.³⁹⁴ The term hidradenitis suppurativa

Figure 15.11 Folliculitis keloidalis. (A) Hair shafts have been extruded into the dermis during the inflammatory destruction of the hair follicles. (B) Fibrosis of the dermis is also present. (H&E)

appears to be the preferred one in Europe.³⁹⁵ The prevalence estimate is 1:300.³⁹⁶ There are recurrent, deep-seated inflammatory nodules, complicated by draining sinuses and subsequent scarring. The disease causes a high degree of morbidity; pain is often a problem.^{397,398} The development of squamous cell carcinoma is a late and rare complication.^{399–403} The tumors arise from the sinus tracts.⁴⁰⁴ Other clinical features include the presence of comedones in retroauricular and apocrine sites,⁴⁰⁵ a female predominance,^{406,407} and a genetic predisposition.^{408–410} Prepubertal onset is rare.⁴¹¹ Associations with lithium therapy,⁴¹² Dowling–Degos disease,⁴¹³ cigarette smoking,^{414–416} obesity,³⁹⁵ and Crohn’s disease have been reported.^{417–419} Other comorbidities include ulcerative colitis; spondyloarthropathy; SAPHO syndrome; certain genetic disorders associated with abnormal keratinization and/or follicular occlusion, including pachyonychia congenita,⁴²⁰ and pyoderma gangrenosum.^{421,422}

In order to better categorize the phenotypes reported in acne inversa, Canoui-Poitaine *et al.* carried out a detailed analysis of 648 patients. Using latent class analysis, they subdivided acne inversa into three types based on anatomic locations of disease, lesional types, family history, and associations with acne.⁴²³ The three types are as follows:

1. Axillary–mammary: this is the typical flexural phenotype seen in European populations
2. Follicular: patients with this type have comedones, other follicular lesions, and severe acne
3. Gluteal: lesions have a predilection for, but are not always located in, the buttocks region; there is a lack of hypertrophic scarring and formation of epidermal cysts.

The disease in one Chinese family was mapped to chromosome 1p21.1–1q25.3.⁴²⁴ Interestingly, frequent losses in chromosomal region 1p21–p22 have been associated with diffuse malignant peritoneal mesothelioma, a rare neoplasm reported recently in association with acne inversa.⁴²⁴ On the other hand, in a family with apparent autosomal dominant inheritance, acne inversa was not linked to chromosome 1p21.1–1q25.3.⁴²⁵

Considerable recent work has been performed to determine the molecular basis for acne inversa. In a study of severe, familial acne inversa, Wang *et al.* discovered loss-of-function mutations of three genes that code important components of the γ -secretase multiprotein complex: *PSENEN*, *PSEN1*, and *NCSTN*.⁴²⁶ Interestingly, mutations in the genes encoding γ -secretase are also implicated in Alzheimer’s

Figure 15.12 Acne inversa (hidradenitis suppurativa). (A) There is acute and chronic inflammation in the dermis and an epithelial downgrowth (probably of follicular origin) 'draining' the area. There is hemorrhage at the deep edge. (B) Inflammation of the apocrine glands is present in this unusual case. (H&E)

disease. γ -Secretase is a transmembrane protease composed of four protein subunits: one catalytic presenilin (PSEN1) subunit and three cofactor subunits (presenilin enhance 2 (PSENEN), nicastrin (NCSTN), and anterior pharynx defective 1 (APH1)).⁴²⁷ γ -Secretase cleaves type I transmembrane proteins that include amyloid precursor protein and Notch. A deficiency of this enzyme in mice leads to occluded hair follicles, believed to be the initiating event in acne inversa.⁴²⁸ Since the initial study, loss-of-function γ -secretase mutations have been identified in other populations with acne inversa. However, it is also the case that not all patients with acne inversa have this mutation; in fact, among 20 consecutive patients with acne inversa in a UK tertiary care setting, none (including 12 patients with a family history) had a γ -secretase mutation.⁴²⁹ It may well be that mutations further along the γ -secretase–Notch signaling pathway are responsible in other cases.⁴³⁰ Correlation of genetic abnormalities with the phenotypes such as those described by Canoui-Poitrine *et al.* will be useful in predicting severe disease and developing targeted, specific therapies. For example, it is believed that the families reported by Wang *et al.* probably have the 'follicular' phenotype.⁴³¹

Host defense mechanisms are usually normal, except in some severe cases in which a reduction in T lymphocytes and the presence of dysfunctional neutrophils have been documented.^{432,433} Monocytes secrete less TNF- α and IL-6 than do cells from healthy controls,⁴³⁴ but TLR2 is strongly expressed.⁴³⁵ A deficiency of IL-22 may also play a role in acne inversa; there is a positive correlation between lesional IL-22 and antimicrobial proteins, and a deficiency of these proteins has been found in acne inversa.⁴³⁶ There is now good evidence that acne inversa is an androgen-dependent disorder,^{437–441} although how this relates to the poral occlusion by keratinous material is uncertain.⁴⁴² This occlusion is followed by an active folliculitis with, in some cases, a secondary apocrinitis and apocrine destruction. Apoeccrine glands, which drain directly onto the epidermal surface, appear to be uninvolved.⁴⁴³ Coagulase-negative staphylococci are the most common isolate,⁴⁴⁴ however, the microbiological flora is not constant.⁴⁴⁹ It is possible that an abnormal immune response against bacteria, colonizing the follicular infundibulum, may be one of the initial events leading to acne inversa.⁴⁴⁵

The treatment of acne inversa (hidradenitis suppurativa) is often ineffective.⁴⁴⁶ This includes preventive measures such as cessation of smoking, weight loss, and avoidance of irritation.³⁹⁶ It also includes the use of topical clindamycin,⁴⁴⁷ rifampicin,⁴⁴⁸ dapsone and corticosteroids, the anti-androgen finasteride,³⁹⁶ infliximab,⁴¹⁶ efalizumab,⁴⁴⁹ etanercept,⁴⁴⁷ carbon dioxide laser,⁴⁵⁰ and wide surgical excision, with healing by secondary intention, when scarring is present.⁴⁵¹

Histopathology⁴⁵²

In established lesions, there is a heavy, mixed inflammatory cell infiltrate in the lower half of the dermis, usually with extension into the subcutis.⁴⁵³ Chronic abscesses are present in active cases, and these may connect with sinus tracts leading to the skin surface (Fig. 15.12). The sinuses are usually lined by stratified squamous epithelium in their outer part. They contain inflammatory and other debris.⁴⁵⁴ Some of these tracts are probably residual follicular structures.^{455,456}

Granulation tissue containing inflammatory cells and occasional foreign body giant cells is present in up to 25% of cases.⁴¹⁸ Epithelioid granulomas were present in one case with coexisting Crohn's disease.⁴¹⁸ Extensive fibrosis with destruction of pilosebaceous follicles and of apocrine and eccrine glands usually ensues. Inflammation of the apocrine glands may be present in the axillary region in approximately 20% of cases.⁴⁵² Perieccrine inflammation is seen in approximately one-third of cases, from all sites.⁴⁴³

A study of 485 operative specimens from 128 patients with acne inversa focused on the early histopathologic changes in this condition. Although there is some heterogeneity in histopathologic patterns, common themes include hyperkeratosis of terminal follicles (89% of cases); hyperplasia of follicular epithelium (80%) – probably the initiating factor of horizontal sinus formation; and prominent perifolliculitis (82%) leading to follicular rupture (24%). Other frequent changes include subepidermal inflammation, psoriasiform acanthosis, prominent acute or chronic dermal inflammation, and involvement of apocrine glands or the subcutis.⁴⁵⁷ These results emphasize the importance of follicular occlusion as a fundamental change in this disease and correlate with recent findings related to abnormalities of the γ -secretase–Notch pathway.

DISSECTING CELLULITIS OF THE SCALP

Dissecting cellulitis of the scalp, also known as perifolliculitis capitis abscedens et suffodiens (Hoffmann's disease), is an extremely rare disease characterized by the appearance of tender, suppurative nodules with interconnecting draining sinuses and subsequent scarring.^{458–460} Patchy alopecia usually overlies the lesions, which have a predilection for the vertex and occipital scalp. There is a predilection for young adult black males.⁴⁶¹ Familial occurrence has been reported.⁴⁶² Dissecting cellulitis may occur alone or in association with the other follicular occlusion diseases – hidradenitis suppurativa and acne conglobata.³⁸⁵ It has also been associated with an arthropathy, which may be axial,⁴⁶³

Figure 15.13 Dissecting cellulitis of the scalp. There are mixed, deep dermal/subcutaneous inflammation and follicular destruction. (H&E)

and a marginal keratitis.⁴⁶⁴ The development of squamous cell carcinoma is a rare complication.⁴⁶⁵

The etiology is unknown, but follicular occlusion is presumed to play a role. Bacterial superinfection appears to be a secondary event.^{466,467} Harsh trauma was implicated in one case.⁴⁶⁸

Treatment with oral isotretinoin has been successful in several cases.^{461,469,470} Quinolone antibiotics may be used as adjuvant therapy.⁴⁶⁷ Electron beam radiation⁴⁷¹ and an 800-nm pulsed diode laser have also been used.⁴⁷² The successful use of infliximab, a monoclonal antibody to TNF- α , has been documented.⁴⁷³

Histopathology⁴⁷⁴

The earliest lesion is a folliculitis and perifolliculitis with a heavy infiltrate of neutrophils leading to abscess formation in the dermis. Draining sinuses may develop, and in later lesions the infiltrate becomes mixed. Variable destruction of follicles ensues (Fig. 15.13).

ACNE CONGLOBATA

Acne conglobata is an uncommon dermatosis, occurring almost exclusively in males and commencing after puberty. There are small and large, tender, inflamed nodules, cysts, and discharging sinuses that eventually heal, leaving disfiguring scars.⁴⁷⁵ Lesions may develop in any hair-bearing area, particularly the trunk, buttocks, and proximal parts of the extremities.⁴⁷⁶ The lesions frequently become secondarily infected with bacteria.⁴⁷⁷ The distribution is much wider than in hidradenitis suppurativa. Acne conglobata has been reported in association with lichen spinulosus in a man seropositive for HIV.⁴⁷⁸ There is also an eruption resembling pityriasis rubra pilaris in these HIV-positive patients.⁴⁷⁹ It has also followed pregnancy.⁴⁸⁰ Malignant degeneration can develop in lesions of acne conglobata of long standing.⁴⁷⁵ There is evidence that single nucleotide polymorphisms of the *TLR4* gene are protective against the development of acne conglobata, despite the presence of *P. acnes*.⁴⁸¹

Isotretinoin, often in conjunction with prednisone, is the preferred treatment for severe acne conglobata. Doxycycline or oral trimethoprim-sulfamethoxazole is used for secondary infections. There is a recent report on the successful use of infliximab in this disease.⁴⁶¹ Good results have also been obtained with etanercept and adalimumab.^{482,483}

Histopathology

The appearances are similar to hidradenitis suppurativa, with deep abscesses and mixed inflammation, foreign body granulomas, and discharging sinuses.⁴⁵⁴ Comedones are often present.

MISCELLANEOUS FOLLICULITIDES

Several folliculitides do not fit appropriately into the categories previously discussed. They include pseudofolliculitis, pruritic folliculitis of pregnancy, and perforating folliculitis. Follicular pustules have also been reported in association with toxic erythema,⁴⁸⁴ cyclosporine therapy,⁴⁸⁵ acute myeloblastic leukemia,⁴⁸⁶ inhibitors of epidermal growth factor receptor,^{131,132,487} and in young individuals with acne treated with systemic steroids.²⁰⁵ A lymphocytic folliculitis was present in a patient with an intensely pruritic eruption on the back, which developed after she stopped dieting.⁴⁸⁸ A florid folliculitis (hyperplastic folliculitis) may develop in organ transplant recipients. It may be related to the taking of cyclosporine by these patients (see later).⁴⁸⁹

The treatment of the folliculitis associated with the epidermal growth factor inhibitors has been successful with topical metronidazole and oral tetracyclines.¹³¹

'Necrotizing infundibular crystalline folliculitis' (NICF) is the term used by Kossard *et al.* for a peculiar folliculitis that developed in a young adult female with a background of acne.⁴⁹⁰ There were folliculocentric facial papules corresponding to filamentous plugs in an amorphous matrix bulging into the upper dermis through a degenerate infundibular wall.⁴⁹⁰ Several additional reports of this condition have appeared in recent years. Denisjuk *et al.* reported nine patients with this condition and seven others who had coincidental findings of NICF near the site of epithelial neoplasms. The mean age was 51 years in the first group and 66 years in the second. There are multiple waxy papules that tend to involve the forehead, neck, and back. In all cases, there were birefringent crystalline deposits in dilated follicular ostia, enclosed by parakeratotic columns and frequently accompanied by necrosis of follicular epithelium. Perifollicular neutrophils, yeast forms, or gram-positive bacteria were found in some cases.⁴⁹¹ Another case showed evidence of perforation; the plug containing the needle-shaped crystals in this case did not clearly involve a follicular unit. It was composed largely of mucin that was Alcian blue and colloidal iron positive. The crystals were partly dissolved when the paraffin block was softened by 10% ammonia solution. By energy-dispersive X-ray spectroscopy, the crystals were shown to be organic in nature, containing carbon but neither calcium nor sodium, and immunohistochemical results argued against keratin tonofilament origin.⁴⁹²

PSEUDOFOLLICULITIS

Pseudofolliculitis is a common disorder of adult black males. It is usually confined to the beard area of the face and neck,⁴⁹³ but rarely the scalp,⁴⁹⁴ pubic area,⁴⁹⁵ and legs⁴⁹⁶ may be involved. Pseudofolliculitis barbae ('razor bumps') refers to lesions of the beard area.⁴⁹⁷ Hypertrophic pseudofolliculitis barbae has been reported in renal transplant recipients receiving cyclosporine.⁴⁹⁸ Pseudofolliculitis consists of papules and pustules in close proximity to hair follicles. Scarring and keloid formation sometimes result.⁴⁹⁹

Pseudofolliculitis is an inflammatory response to an ingrown hair. Hair shafts in black people have a tendency to form tight coils and, following shaving, the sharp ends may pierce the skin adjacent to the orifice of the follicles.⁴⁸⁹ Dermoscopy has been used to confirm the diagnosis.⁴⁹⁷

The treatment of pseudofolliculitis is challenging. Behavioral changes with a minimization of overshaving may assist.¹⁶³ Benzoyl peroxide,

clindamycin, and retinoids have been used. Surgical or laser depilation may be necessary.⁴⁹⁷ The Nd:YAG laser is a safe and effective option for reducing hair and subsequent papule formation.⁵⁰⁰

Histopathology⁴⁹³

Surprisingly, little has been written about the histopathology of this common disorder. There are perifollicular inflammatory foci that are initially suppurative. Small foreign body granulomas and a mixed inflammatory cell infiltrate are present in older lesions. Variable scarring may ensue. In some instances, epithelium grows down from the surface to encase both the hair and the inflammatory response, assisting in their eventual transepithelial elimination.

Dermoscopy is relatively unique, showing a gray-blue, thick curved line and adjacent red lines (probably reactive vessels) upon a structureless pattern.⁵⁰¹

PRURITIC FOLLICULITIS OF PREGNANCY

Pruritic folliculitis of pregnancy is a rare dermatosis in which pruritic, erythematous papules develop in a widespread distribution in the latter half of pregnancy.⁵⁰² The lesions clear spontaneously at delivery or in the postpartum period. There is no adverse effect on fetal well-being.⁵⁰³ The etiology is unknown, but on the basis of a case with elevated androgens, it has been suggested that this condition is a 'form of hormonally induced acne'.⁵⁰⁴ This finding has not been confirmed in a subsequent study.⁵⁰⁵ *Malassezia* yeasts do not appear to be the cause either.^{505,506}

Histopathology⁵⁰²

The appearances are those of an acute folliculitis, sometimes resulting in destruction of follicular walls and abscess formation in the adjacent dermis. Perifollicular granulomas may be seen in late lesions.⁵⁰⁷ No organisms have been noted in the cases reported so far.

PERFORATING FOLLICULITIS

Perforating folliculitis is manifested by discrete, keratotic, follicular papules with a predilection for the extensor surfaces of the extremities and the buttocks.⁵⁰⁸ It may persist for months or years, although periods of remission often occur. Disease associations have included psoriasis,⁵⁰⁹ juvenile acanthosis nigricans, HIV infection,⁵¹⁰ primary sclerosing cholangitis,^{511,512} and renal failure, often in association with hemodialysis.^{508,513} It has been reported following the use of the inhibitors of TNF- α , infliximab and etanercept.⁵¹⁴

The features of perforating folliculitis associated with renal failure (see p. 373) may overlap those of reactive perforating collagenosis and Kyrle's disease⁵⁰⁸ (the latter disease has been regarded by some as a variant of perforating folliculitis).⁵¹⁵ Lesions associated with renal failure are often pruritic, in contrast to the asymptomatic lesions of the majority of cases.⁵¹⁶

The etiology of perforating folliculitis is unknown, although minor mechanical trauma may play a role. It has been suggested that perforation of the epithelium is the primary event and that it is not a primary disorder of transepithelial elimination.⁵¹⁶ Perforating folliculitis has been seen in patients receiving sorafenib and nilotinib. Both agents inhibit c-kit and platelet-derived growth factor receptor (PDGF-R), a kinase involved in the hair follicle cycle.^{517,518}

Histopathology^{198,508}

There is a dilated follicular infundibulum filled with keratinous and cellular debris. A curled hair shaft is sometimes present. The follicular epithelium is disrupted in one or more areas in the infundibulum (Fig. 15.14). The adjacent dermis shows degenerative changes involving the connective tissue, and sometimes collagen and elastic fibers are seen

Figure 15.14 Perforating folliculitis. An early stage lesion. The follicular epithelium shows disruption of its lateral wall. A pigmented hair shaft fragment is present in the follicular lumen. Cell debris and degenerated connective tissue elements can be seen entering the perforation. (H&E)

entering the perforation (Fig. 15.15). The elastic fibers are not increased as in elastosis perforans serpiginosa. A variable inflammatory reaction is present in the dermis in this region, and sometimes a granulomatous perifolliculitis develops. Although a few neutrophils may be present in the infiltrate, they are never as plentiful as in pityrosporum folliculitis, which often ruptures into the dermis. Sometimes the follicular localization of perforating folliculitis is not appreciated unless serial sections are examined. A deep scarring, or profunda, type has been described in which perforation occurs at several different levels of the follicle, with a more extensive granulomatous infiltrate and destruction of the follicular epithelium and sebaceous gland. Pili multigemini has been associated with folliculitis perforans profunda.⁵¹⁹

In chronic renal failure, the lesion begins as a follicular pustule that perforates, resulting in a suppurative and granulomatous perifolliculitis.⁵²⁰ Late lesions may develop epidermal features of prurigo nodularis.^{520,521}

FOLLICULAR TOXIC PUSTULODERMA

The term 'follicular toxic pustuloderma' has been used for an acute pustular eruption with follicular localization. Most cases have been associated with the ingestion of drugs, particularly antibiotics, although in others an enterovirus infection has been incriminated.⁵²² Because the lesions are not always follicle-based, the terms 'toxic pustuloderma' and 'acute generalized exanthematous pustulosis' are now used (see p. 145).

STERILE NEUTROPHILIC FOLLICULITIS WITH PERIFOLLICULAR VASCULOPATHY

The term 'sterile neutrophilic folliculitis with perifollicular vasculopathy' was coined by Magro and Crowson for a distinctive cutaneous reaction pattern, usually accompanying systemic diseases such as inflammatory bowel disease, Reiter's disease, Behçet's disease, hepatitis B, and various connective tissue diseases.⁵²³ It may present clinically as a folliculitis or a vasculitis or with vesiculopustular or acneiform lesions, predominantly on the legs, arms, and upper back. Arthritis, fever, and malaise are often present.

Figure 15.15 Perforating folliculitis. Degenerate collagen and elastic tissue are entering the perforated follicle. The patient had chronic renal failure. (H&E)

Histopathology

The reported cases showed a neutrophilic or suppurative and granulomatous folliculitis accompanied by a folliculocentric neutrophilic vascular reaction of Sweet's-like or leukocytoclastic vasculitis subtypes (Fig. 15.16).⁵²³

PSEUDOLYMPHOMATOUS FOLLICULITIS

Pseudolymphomatous folliculitis is a subset of cutaneous lymphoid hyperplasia that is found at all ages and in both sexes.⁵²⁴ It is almost exclusively a solitary lesion on the face measuring approximately 1 cm in diameter.⁵²⁵ The lesions often regress after incisional biopsy.

A review of 55 cases of cutaneous lymphoid hyperplasia ('pseudolymphoma') from Japan revealed 19 cases that were reclassified as pseudolymphomatous folliculitis.⁵²⁶

Histopathology⁵²⁴

Pseudolymphomatous folliculitis has a dense dermal lymphocytic infiltrate simulating cutaneous lymphoma. The walls of the hair follicles

Figure 15.16 Sterile neutrophilic folliculitis with perifollicular vasculopathy. This case was associated with Behçet's disease. (A) Initial sections show an intact portion of a follicle with a surrounding vascular reaction. (B) Deeper sections show neutrophilic folliculitis with destruction of the superficial portion of the follicle. (C) Detail of the surrounding vascular changes, showing leukocytoclastic vasculitis. (H&E $\times 3$)

are enlarged and irregularly deformed with their epithelial outline blurred by a lymphocytic infiltrate. Atypical lymphocytes are often present, leading to a misdiagnosis of lymphoma. Of the 15 cases reported in one series, 10 were composed predominantly of B cells and the remainder predominantly of T cells.⁵²⁴ Increased numbers of

dendritic cells expressing S100 and CD1a are present in the perifollicular region. In the series of 19 cases from Japan, pseudolymphomatous folliculitis was identified by the presence of activated pilosebaceous units with abundant CD1a⁺, S100 protein⁺ T-cell-activated dendritic cells.⁵²⁶ The relationship between this entity and Kossard's folliculotropic T-cell lymphocytosis is unknown because CD1a and S100 were not performed.⁵²⁷ The paper by Kazakov *et al.* presented the largest series to date, included 42 cases consistent with pseudolymphomatous folliculitis and 11 cases of true lymphoma.⁵²⁸ The microscopic features were largely as described previously, including also eccrine or apocrine ductal hyperplasia, infiltration of deep subcutis or skeletal muscle, single file infiltration, and some large atypical cells. Other cell types in addition to lymphocytes included plasma cells and epithelioid macrophages. T-cell predominance was noted. Plasma cells were polyclonal. Three of 30 tested cases were positive for herpes simplex virus-1, a condition known to be associated with atypical lymphoid infiltrates. Rearrangements of T-cell receptor genes (19 cases) and immunoglobulin heavy-chain genes (3 cases) were identified; there were no differences between clonal and nonclonal cases in terms of clinical, histopathologic, or immunohistochemical features.⁵²⁸ Although the epidermis is typically spared in pseudolymphomatous folliculitis, a case with focal epidermotropism overlying involved follicles has been reported.⁵²⁹

HAIR SHAFT ABNORMALITIES

Hair shafts may be abnormal as a result of an intrinsic defect, either congenital or acquired, in the hair shaft itself or because of the deposition or attachment of extraneous matter such as fungi, bacteria, or lacquer.⁵³⁰ In either case, structural weakness of the hair shaft may occur; the resulting hair breakage and loss may be severe enough to produce alopecia. Some hair shaft abnormalities may be a component of a systemic disease.⁵³¹ Examination of scalp hair samples may aid in the diagnosis of pediatric disorders.⁵³²

Brief mention is made of hair graying, a variation in the human hair of considerable interest to persons involved. Graying appears to be a consequence of an overall and specific depletion of melanocytes in the hair bulbs and the outer root sheath.⁵³³ Hair pigmentation is regulated by several factors, including the interaction of the ligand stem cell factor (SCF) with its class III receptor tyrosine kinase, c-kit. An interruption of SCF/c-kit signal transduction results in hair depigmentation.⁵³⁴ Treatment with some of the newer tyrosine kinase inhibitors may result in reversible hair depigmentation.⁵³⁴ Gray hair has developed in children taking triptorelin, a drug used for the treatment of precocious puberty.⁵³⁵

Several clinical classifications of hair shaft abnormalities have been proposed.^{530,536-538} One such classification distinguishes the structural defects with increased fragility from those without this characteristic because only the cases in the former group (monilethrix, pili torti, trichorrhexis nodosa, trichothiodystrophy, Netherton's syndrome, and Menkes' syndrome) present clinically with patchy or diffuse alopecia.⁵³⁶ Another clinical approach has been to separate those conditions associated with 'unruly hair', namely woolly hair, acquired progressive kinking of hair, pili torti, and rare cases associated with brain growth deficiency.⁵³⁹ One case that defies orderly classification has been called '**cutaneous pili migrans**'. In that case, a 7-cm-long submerged hair extended as a blue line just below the skin surface.⁵⁴⁰ There was no associated inflammation. Other examples of this phenomenon, resulting from implantation of exogenous hair shafts, have been reported. One case involved the glans penis,⁵⁴¹ and another involved the sole of the foot of a child.⁵⁴²

The classification to be followed here is morphologically based and is similar to the one proposed by Whiting.⁵³⁰ Four major groups exist:

- Fractures of hair shafts
- Irregularities of hair shafts
- Coiling and twisting abnormalities
- Extraneous matter on hair shafts.

FRACTURES OF HAIR SHAFTS

The hair shaft fracture group of abnormalities is the most important because it may lead to alopecia. Sometimes, however, these abnormalities occur sporadically or intermittently,⁵⁴³ involving only isolated hairs as an incidental phenomenon. This is particularly likely to occur in those who subject their hair to physical or chemical trauma. More than one type of fracture may be present in these cases.⁵⁴⁴ The following types of fractures are considered:

- Trichorrhexis nodosa
- Trichoschisis
- Trichoclasia
- Trichorrhexis invaginata
- Tapered fracture
- Trichoptilosis
- Trichoteiromania
- Trichotemnomania.

TRICHOORRHEXIS NODOSA

Trichorrhexis nodosa is characterized by one or more small, beaded swellings along the hair shaft, corresponding to sites that fracture easily. Scalp hair is most often involved, although the genital region may also be affected.⁵⁴⁵ Trichorrhexis nodosa may be generalized or localized.⁵⁴⁶ Alopecia may result because the hairs fracture easily. A case diagnosed by trichoscopy (a form of dermoscopy) was shown to be associated with nail dystrophy.⁵⁴⁷

The basic cause of trichorrhexis nodosa is prolonged mechanical trauma or chemical insults, although a contributing factor in some instances is an inherent weakness of the hair shaft. This weakness may result from a specific pilar dystrophy such as pili torti, monilethrix or trichorrhexis invaginata, or from an inborn error of metabolism affecting the hair such as citrullinemia (OMIM 215700),⁵⁴⁸ arginosuccinic aminoaciduria (OMIM 207900),⁵⁴⁹ Menkes' syndrome (OMIM 309400),⁵⁵⁰ trichothiodystrophy (see later), or biotinidase deficiency.^{537,545,551-555} This latter group of abnormalities is quite rare, but they usually form the basis of hereditary cases of trichorrhexis nodosa.⁵⁴⁵ Trichorrhexis nodosa is also associated with other rare syndromes, such as one that also includes intractable diarrhea of infancy, dysmorphism, and cirrhosis.⁵⁵⁶ Neurocutaneous features may accompany the trichorrhexis nodosa syndrome (OMIM 275550).

Trichothiodystrophy (OMIM 601675) refers to a rare group of autosomal recessive disorders that have in common short brittle hair with a sulfur content less than 50% of normal.^{545,557-561} This results from a deficiency of the sulfur-containing amino acid cysteine in the cuticle and cortex.⁵⁶²⁻⁵⁶⁴ A defect in excision repair of ultraviolet damage in fibroblasts has been detected in many patients. Unlike xeroderma pigmentosum, in which this defect also occurs, there is no increase in skin cancer.^{565,566} Most patients exhibit mutations on the two alleles of the *XPD* (*ERCC2*) gene, mapped to 19q13.2, although rarely a mutated *XPB* (*ERCC3*) gene, mapped to 2q21, or *TTDA* gene may be involved.^{567,568} Further information is provided in an excellent review by Itin and colleagues.⁵⁵⁹ Trichothiodystrophy is often associated with brittle hair, impaired intelligence, decreased fertility, and short stature (BIDS syndrome; OMIM 234050), sometimes combined with ichthyosis (IBIDS syndrome),^{562,569} osteosclerosis (SIBIDS syndrome),⁵⁷⁰

Figure 15.17 *Trichorrhexis nodosa* with its characteristic fracturing of the hair shaft.

or photosensitivity (PIBIDS syndrome).^{571,572} It has been suggested, and confirmed in mutant (TTD) mice, that the neurological features seen in some of these related syndromes are due to thyroid hormone deficiency resulting from *XPD* mutations.⁵⁶⁷

Histopathology

The expanded areas of the hair shaft are composed of frayed cortical fibers that usually remain attached.⁵⁴⁴ This appearance has been likened to the splayed bristles of two paint brushes (or brooms) thrust into one another (Fig. 15.17).⁵⁵⁷ The cuticular cells become disrupted prior to this splaying of the cortical fibers.

In black people, trauma-related cases of trichorrhexis nodosa usually affect the proximal part of the hair shaft, whereas in white and Oriental races, the distal part is more often affected.⁵³⁰

In individuals with underlying **trichothiodystrophy**, striking bright and dark bands are seen with polarized light (tiger-tail appearance).^{560,561,569,571,573} Lesions resembling trichorrhexis nodosa and trichoschisis may be present.⁵⁷⁴ On scanning electron microscopy, the cuticle scales are often damaged or absent, and there may be abnormal ridging of the surface.

TRICHOSCHISIS

Trichoschisis is a clean transverse fracture of the hair shaft through the cuticle and cortex.⁵³⁰ It is usually seen in the brittle hair associated with trichothiodystrophy (discussed previously).

Histopathology

Trichoschisis involves a clean transverse break in the shaft (Fig. 15.18).⁵³⁰

TRICHOCLASIS

There is a transverse or oblique fracture of the shaft with irregular borders and a cuticle that is partly intact.⁵³⁰ As such, it resembles a greenstick fracture.⁵³⁰ It does not indicate any specific underlying systemic disease but, rather, may follow trauma to the hair or be associated with pili torti, monilethrix, or other hair shaft abnormalities (see later).

Figure 15.18 *Trichoschisis*. There is a clean break in the shaft.

TRICHORRHEXIS INVAGINATA

Trichorrhexis invaginata (bamboo hair) is a rare but unique abnormality of the hair shaft in which there are nodose swellings that give the hair an appearance reminiscent of a bamboo stem.⁵⁷⁵ The scalp hair is usually short, dull, and friable, and the eyebrows and eyelashes may be sparse.⁵⁵⁷ It is one of the hair anomalies associated with Netherton's syndrome (OMIM 256500), an autosomal recessive disorder in which there is also ichthyosis linearis circumflexa or some other ichthyosiform dermatosis (see p. 288).^{566,575} This hair shaft anomaly is seen less characteristically as a sporadic change following trauma or in association with other hair shaft abnormalities.^{530,575}

Trichorrhexis invaginata may result from a transient defect of keratinization of the hair shaft due to incomplete cysteine linkages, leading to softness of the cortex at the point of disruption.⁵⁷⁵

Histopathology

There is a cup-like expansion of the proximal part of the hair shaft that surrounds the club-shaped distal segment in the manner of a ball-and-socket joint.⁵³⁰ If only the proximal half of the invaginate node is present, the appearances have been described as 'golf-tee' hairs.⁵⁷⁶

Transmission electron microscopy shows cleavages and electron-dense depositions in the cortex.⁵⁷⁵

TAPERED FRACTURES

Tapered fractures refer to a progressive narrowing of the emerging hair shaft as a result of inhibition of protein synthesis in the hair root.⁵³⁰ Fracture of the shaft may occur near the skin surface. Tapered fractures ('pencil-pointing') are seen in anagen effluvium caused by cytotoxic drugs.⁵³⁰

TRICHOPTILOSIS

Trichoptilosis refers to longitudinal splitting or fraying of the distal part of the hair shaft as a result of persistent trauma.⁵⁷⁷ It results from separation of the longitudinal cortical fibers following loss of the cuticle from wear and tear.⁵³⁰ A rare variant with the split in the center of the hair and reconstitution of the shaft distal to this has

been reported.^{578,579} Other hair shaft abnormalities may also be present.

TRICHOTEIROMANIA

Trichoteiromania is self-inflicted damage to the hair resulting from rubbing of the hair.⁵⁸⁰ This causes splitting and breaking of the hairs and discrete patches of alopecia.⁵⁸⁰

TRICHOTEMNOMANIA

This factitious disorder is characterized by hair loss resulting from an obsessive-compulsive habit of cutting the hair with scissors or with a razor. It has been associated with trichotillomania.⁵⁸¹ Despite the alopecia, all infundibula are filled with a hair shaft.⁵⁸²

IRREGULARITIES OF HAIR SHAFTS

This group of hair shaft abnormalities is characterized by various morphological irregularities in the hair. A common change, which is sometimes classified as a discrete abnormality, is longitudinal grooving of the hair. It is usually an isolated phenomenon of no clinical importance, although rarely it is widespread and associated with a form of congenital hypotrichosis or with trichothiodystrophy.⁵³⁰ It is not considered further. Enlargement of the hair shaft (trichomegaly) is discussed in this section.

Included in this group are the following entities:

- Pili canaliculati et trianguli
- Pili bifurcati
- Pili multigemini
- Trichostasis spinulosa
- Pili annulati
- Monilethrix
- Tapered hairs
- Bubble hair
- Trichomegaly.

Each of these entities is considered in turn.

PILI CANALICULATI ET TRIANGULI

Pili canaliculati et trianguli (pili canaliculi; OMIM 191480), a rare disorder of the hair shaft, is also known as the uncombable hair syndrome,^{583,584} cheveux incoiffables,⁵⁸⁵ and the spun-glass hair syndrome.^{586–588} The hair is drier, glossier, and lighter, and it is unmanageable in that it does not lie flat when combed.^{589,590} It may be sparse.⁵⁹¹ The condition derives its name from the longitudinal canalicular depression in one side of the shaft and its triangular or kidney shape in cross section.^{585,589} For clinical change to be apparent, approximately 50% of hairs must be affected with this abnormality.⁵⁹² It may result from a disorder of keratinization of the hair.⁵³⁷ This hair shaft abnormality has been reported in patients with ectodermal dysplasia.^{593,594} This has been called Bork syndrome (OMIM 191482).

Straight hair nevus, a localized disorder in which the involved hairs are short and straight – in contrast to the usual woolly hair of black people, in whom this condition has been described – has been regarded as a localized form of uncombable hair.⁵⁹⁵ However, note that in straight hair nevus there may be an associated epidermal nevus; furthermore, the hairs are normal in cross section, in contrast to pili canaliculati et trianguli.⁵⁹⁶ It has also followed the use of IFN- α and ribavirin in the treatment of hepatitis C infection.⁵⁹⁷

Histopathology

The hairs appear normal on light microscopy.⁵⁸⁷ Under polarized light, however, they have a diagnostic homogeneous band on one edge.⁵⁸⁷ Under stereomicroscopy, the grooves are easily seen. Paraffin-blocked hairs have a triangular or kidney-shaped appearance on transverse section.⁵⁸⁷ The shape is confirmed by scanning electron microscopy, which also shows the longitudinal depression of the shaft resembling a canal.^{557,587} Approximately 30% of hairs in some patients have torsions.⁵⁹⁸

Electron microscopy

There are ultrastructural changes in the inner root sheath consisting of tonofilament-desmosomal detachment and tonofilament clumping within inner root sheath cells.⁵⁹⁹

PILI BIFURCATI

In the condition known as pili bifurcati, hairs show intermittent bifurcations of the shaft that subsequently rejoin further along the shaft to form a normal structure.⁶⁰⁰ Unlike trichoptilosis, which it superficially resembles, each ramus of the bifurcated segments is invested by its own cuticle.⁶⁰⁰ This abnormality has been regarded as a restricted form of pili multigemini.⁵³⁰

PILI MULTIGEMINI

Pili multigemini is a rare malformation of the pilary apparatus associated with the emergence of multiple hairs from a follicular canal, which in turn is composed of as many papillae as there are hairs.^{601,602} These multigeminate follicles may arise on the face or the scalp. It differs from *tufted-hair folliculitis*, in which distinctive tufts of multiple hairs emerge from a single follicular orifice into which several complete follicles open (see p. 496).

TRICHOSTASIS SPINULOSA

Trichostasis spinulosa presents either as asymptomatic, comedone-like lesions on the nose⁶⁰³ or as mildly pruritic hyperkeratotic papules on the upper trunk or arms.^{530,604–606} With a hand lens, multiple vellus hairs can sometimes be seen protruding from the patulous follicles. There is retention of telogen hairs within the follicles, although the reason for this is unknown.⁶⁰⁴ Widespread trichostasis spinulosa has been reported in a patient on hemodialysis for chronic renal failure.⁶⁰⁷ There is also a possible association with the prolonged topical application of a corticosteroid cream.⁶⁰⁸

Histopathology⁶⁰⁵

Multiple hairs are enveloped in a keratinous sheath within a dilated hair follicle. The keratin plug may protrude above the skin surface. There is only one hair matrix and papilla at the base of the follicle,⁵³⁰ in contrast to pili multigemini. Sometimes there is mild perifollicular inflammation.

PILI ANNULATI

The condition of pili annulati (ringed hairs; OMIM 180600) is a rare, familial (autosomal dominant) or sporadic anomaly in which there are alternating light and dark bands along the shaft, when viewed by reflected light.^{554,609,610} Axillary hair is occasionally affected. An association with alopecia areata has been reported.^{611–613} In one case, there was clinical disappearance of the disorder in the regrown hair following

an episode of alopecia areata, although banding was still present in 20% of the hairs on light microscopy.⁶¹⁴

The light bands are due to clusters of abnormal, air-filled cavities that appear to result from insufficient production of the interfibrillar matrix.^{609,615} Various weathering patterns may be seen in involved hair shafts.^{616–618}

The term '**pseudopili annulati**' refers to the presence of light and dark bands when slightly flattened or twisted hair is examined under reflected light.^{619,620} It is thought to be a variant of normal hair and to have no clinical significance.⁵³⁰

Histopathology

The alternating light and dark bands occur approximately every 0.5 mm along the shaft when viewed by reflected light.^{615,621} The periodic bands become less frequent distally in the hair shaft.⁶²² Features of weathering are sometimes present.⁶²² Scanning electron microscopy reveals the presence of many small holes within the cortex as well as an irregular arrangement of the cuticular scales.⁶¹⁵ Cytokeratin expression is the same as that for normal hair.⁶²³ Electron microscopy of the associated hair follicles shows a reduplicated lamina densa in the region of the root bulb.⁶²⁴

MONILETHRIX

In monilethrix (OMIM 158000), the hairs have a beaded or moniliform appearance as a result of a periodic decrease in the diameter of the hair.^{625,626} Inheritance is usually as an autosomal dominant trait with high gene penetrance but variable expressivity (see later).⁵³⁰

The hair is susceptible to fracture at the narrower internodal regions, leading to short hair and hair loss.⁶²⁷ The occipital region is usually involved soon after birth, and the affected area slowly extends.⁵³⁷ Other hairy areas may also be involved. Some improvement occurs with age, and occasionally there is spontaneous remission at puberty.⁵⁵⁷

The defect leading to monilethrix may result from a periodic dysfunction of the hair matrix.^{625,628,629} Abnormalities also exist in the inner root sheath adjacent to the zones of abnormal shaft thinning. Transmission electron microscopy has shown an abnormal cortex with areas of homogeneous nonfibrillar material and a deviated axis of some microfibrils.⁶³⁰

The gene responsible for monilethrix maps to the region on chromosome 12 (12q13) containing the type II keratin cluster, which includes the basic type II trichocyte keratins.^{631,632} The defect may involve one of three keratin genes: *KRTHB6* (*KRT86*), *KRTHB1* (*KRT81*), and *KRTHB3* (*KRT83*).^{633,634} Several different mutations have been found.^{635,636} Nail defects appear common with *KRTHB1* defects.⁶³⁴ Monilethrix may be associated with keratosis pilaris and with various ectodermal anomalies. These other syndromes are not well characterized.⁶³⁷

Pseudomonilethrix (OMIM 177750) is characterized by nodes placed at irregular intervals along the hair shaft. It may be an autosomal dominant disorder producing hypotrichosis of the entire scalp or just the occipital area, an acquired condition associated with various hair fragility disorders, and an iatrogenic condition.⁶³⁸ The latter form may be the result of the compression of normal or fragile hairs between glass slides, prior to their microscopic examination.⁶³⁹

Histopathology

The elliptical nodes of monilethrix, which are 0.7–1 mm apart, are separated by tapered internodes lacking a medulla (Fig. 15.19).⁵³⁷ Scanning electron microscopy shows weathering changes with loss of cuticular cells and the presence of longitudinal grooves on the internodal shaft.^{530,625} The distal end of the hair shaft may show no beading; the changes are best seen in the proximal shaft.⁶⁴⁰

Fractures and trichorrhexis nodosa may also be present.

Figure 15.19 Monilethrix. The tapered internodal regions lack a medulla.

TAPERED HAIRS

Tapered hairs can arise in the same way as tapered fractures, and they may also occur in association with other abnormalities of the hair shaft.⁵³⁰ Several distinct variants have been described. The *Pohl–Pinkus mark* is an isolated narrowing of the hair shaft that coincides with a surgical operation or some other traumatic episode.⁵³⁰ This narrowing is not as abrupt in the *bayonet hair*, which may possibly be a form of the Pohl–Pinkus mark.⁵³⁰ Newly growing anagen hairs often have a tapered, hypopigmented top.

BUBBLE HAIR

Bubble hair is a rare abnormality characterized by a large cavity in the shaft on scanning electron microscopy and an unusual 'bubble' appearance on light microscopy.⁶⁴¹ It presents with a localized area of brittle, easily broken hairs on the scalp.⁶⁴² The abnormality can be reproduced by heat, suggesting that hair dryers that overheat may be responsible.^{470,643–645} Bubble hair has developed following the use of a hot iron on wet hair as a straightening procedure.⁶⁴⁶

TRICHOMEGALY

Trichomegaly (OMIM 190330) refers to an enlargement and hypertrichosis of the eyelashes. It may be associated with more generalized hypertrichosis or with involvement of the eyebrows as well. There is a congenital and an acquired form. Interest in this condition has followed its association with various drugs such as IFN- α -2a and -2b, topiramate, cyclosporine, latanoprost, and the EGF-R inhibitors gefitinib,^{140,647,648} erlotinib,⁶⁴⁹ cetuximab,⁶⁵⁰ and panitumumab.⁶⁵¹ A variant associated with mental retardation and retinal degeneration (OMIM 275400) also occurs. An excellent review of eyelash trichomegaly and its disease associations has been written by Paul and colleagues.⁶⁵²

COILING AND TWISTING ABNORMALITIES

As the heading suggests, the hair shafts in this group of disorders adopt various configurations.⁵³⁰ The following are involved:

- Pili torti
- Woolly hair

- Acquired progressive kinking
- Curly hair
- Trichonodosis
- Circle and rolled hair.

The condition of pili torti is the most important member of this group, whereas trichonodosis and circle hairs are of little consequence.

PILI TORTI

Pili torti (OMIM 261900) result from a structural defect in which the hair shaft is twisted on its axis at irregular intervals, with flattening of the hair at the sites of twisting.⁶⁵³ This leads to increased fragility, particularly in areas subjected to trauma.⁵³⁹ There are several clinical settings in which pili torti can occur.⁵³⁰

The rare congenital (Ronchese) type presents at birth or soon after, with a localized area of alopecia or short hair that gradually spreads.⁵³⁰ Sites other than the scalp may be affected. Pili torti may occur alone or in association with other syndromes, particularly of ectodermal type.⁵³⁸ These include Bazex's, Crandall's, and Bjornstad's syndromes^{654,655} as well as hypohidrotic ectodermal dysplasia.⁵³⁹ They also occur in citrullinemia (OMIM 215700)⁶⁵³ and in Menkes' kinky hair syndrome.^{537,557} Bjornstad's syndrome (OMIM 262000) combines pili torti with congenital hearing loss.^{656,657} The responsible gene maps to chromosome 2q34–q36. There is a mutation in the *BSC1L* gene, which encodes an ATPase required for the assembly of a mitochondrial complex.⁵⁴⁸ Crandall's syndrome combines pili torti, hearing loss, hypogonadism, and, rarely, mental retardation.⁵⁴⁸ In Menkes' syndrome (OMIM 309400), the hair may show defects other than pili torti, including trichorrhexis nodosa, trichoclasia, and irregular twisting.⁶⁵⁸ The gene maps to chromosome Xq13.

Postpubertal onset has also been recorded (Beare type).⁵³⁹ Involvement of multiple hair-bearing sites and mental retardation are usually features of this variant. An acquired form of pili torti has been described as a result of trauma, associated with cicatricial alopecia, following the use of synthetic retinoids (isotretinoin),⁶⁵⁹ and on the abdomen and thighs of hirsute males and females.⁶⁶⁰ It has also been reported in anorexia nervosa.⁶⁶¹ Pili torti of early onset may improve with age.

'Corkscrew' hairs, an exaggeration of pili torti, have been reported in patients with ectodermal dysplasia.^{662,663} The presence of a longitudinal groove on the hair shaft has led to 'corkscrew' hairs being called pili torti et canaliculi.⁶⁶³ This abnormality can also be seen in hereditary congenital hypotrichosis of Marie–Unna (see p. 483).

Histopathology

The twisting of the shaft is easily appreciated on light microscopy (Fig. 15.20). Fractures and trichorrhexis nodosa are sometimes present as well.⁶²⁷ Corkscrew hairs combine torsion and longitudinal grooving.

Curvatures and twisting have been recorded in the hair follicles that produce pili torti.^{530,537}

WOOLLY HAIR

Woolly hair is very curly hair that is difficult to style. It is normal in most black races, but in white races it occurs in several different clinical settings,^{530,554,664,665} including an autosomal dominant form (OMIM 194300) that affects the entire scalp (the hereditary type). Shimomura *et al.* reported a mutation of the *KRT74* gene in a Pakistani family with autosomal dominant woolly hair. This gene encodes the inner root sheath-specific soft keratin 74.⁶⁶⁶ An autosomal recessive form (the familial type; OMIM 278150) is due to a mutation in the *PKRY5* gene at 13q14.12–q14.2. There is a diffuse partial form, in which shorter, finer, curly hair is interspersed with normal hair,⁶⁶⁴ and a well-

Figure 15.20 Pili torti. Twisting of the hair shaft is present.

demarcated localized form (woolly hair nevus), which may be associated with an ipsilateral epidermal nevus.^{667–671} Acquired progressive kinking of the hair (see later) is sometimes included as a variant of woolly hair.⁵³⁷ Woolly hair has been reported in association with loose anagen hair,⁶⁷² hair shaft fragility,⁶⁷³ and skin fragility (OMIM 607655) due to a mutation in the desmoplakin gene (see p. 137). Woolly hair has also been associated with hypotrichosis, an everted lip and malformation of the ear (OMIM 278200), and several ectodermal dysplasias, usually including palmoplantar keratoderma as well.^{674,675} Specific associations include Naxos disease (OMIM 601214; see p. 295), Noonan syndrome (OMIM 163950), cardiofaciocutaneous syndrome (OMIM 115150), and keratosis pilaris (OMIM 604093) and its variant ulerythema ophryogenes (see p. 499).⁶⁷⁶

Histopathology

The hairs are usually normal on light microscopy, although on cross section the shaft diameter is sometimes reduced.⁵³⁰ In woolly hair nevus, the hairs are more oval on cross section than normal hairs;⁶⁶⁴ a case with triangular hairs has been reported.⁶⁶⁷ The follicles may be somewhat curved in woolly hair nevus.

ACQUIRED PROGRESSIVE KINKING

Acquired progressive kinking of the hair shaft is rare. It is sometimes considered to be a variant of woolly hair, but it is best regarded as a distinct entity on the basis of its onset at or after puberty, the involvement of certain regions of the scalp rather than the entire scalp, and the tendency for affected hair to resemble pubic hair both in texture and in color.^{677–680} Acquired progressive kinking of the hair tends to occur in males who subsequently develop a male pattern alopecia of fairly rapid onset.^{677,681–683} 'Whisker hair', which occurs not uncommonly about the ears, is probably a variant.^{530,677,683,684}

Histopathology

There is usually some flattening of the hair shafts with partial twisting at irregular intervals.⁶⁸¹ Longitudinal canalicular grooves can be demonstrated on scanning electron microscopy.^{681,685}

CURLY HAIR

Curly hair, in which there are large loose spiral locks, can be seen in many genetic syndromes including trichodentoosseous (TDO)

syndrome (OMIM 190320),⁵⁶⁸ Costello's syndrome (OMIM 218040), CHAND (curly hair, ankyloblepharon, and nail dysplasia) syndrome (OMIM 214350), and Noonan's syndrome (OMIM 163950).⁵⁴⁸ Curly hair is also a feature of giant axonal neuropathy (OMIM 256850), associated with mutations of the *GAN* gene, which lead to cytoskeletal protein impairment and a disorder of intermediate filaments. In fact, the absence of curly hair in this syndrome is associated with a milder phenotype, with better motor function.⁶⁸⁶ The TDO syndrome is due to a mutation in the *DLX3* gene on chromosome 17q21. It is a homeobox gene important for embryonic development.⁵⁴⁸

TRICHONODOSIS

Trichonodosis (knotted hair) is usually an incidental finding in individuals with various lengths and types of scalp hair, particularly those with curly or kinky hair.^{687,688} Knots are very common in curly African hair, leading to fracturing and breaking when combed. African hair length is less than that of white people, possibly because of the hair loss associated with the combing of knotted hair.⁶⁸⁹ There may be a single or a double knot. Various hair shaft abnormalities of a secondary nature may be present in and adjacent to the knots.⁵³⁰

Multiple large knots involving body hairs have been reported. The hairs show an unusual twisting and matting.⁶⁹⁰

Hair matting is a rare acquired condition characterized by irreversible tangling of hair. It has many causes other than trichonodosis, including the following: hair density and coiling; chemical and physical treatments to the hair, including the use of conditioners;⁶⁹¹ frequent combing;⁶⁹² and neglect.^{693,694} The original term *plica neuropathica* is sometimes used for this condition.^{695,696} *Plica polonica* refers to the same phenomenon.⁶⁹⁷

CIRCLE AND ROLLED HAIR

Circle hair presents as a black circle related to hair follicles as the result of a hair shaft becoming coiled into a circle under a thin transparent roof of stratum corneum.^{698,699} The cause of this abnormality is unknown, but it may be seen in middle-aged men on the back, abdomen, and thighs.⁶⁹⁸ The case reported as pili migrans has some similarities (see p. 474).

Rolled hair (the term is sometimes used interchangeably with circle hair) refers to a common disorder of hair growth in which the hairs are irregularly coiled but do not form a perfect circle.⁷⁰⁰ It is usually associated with some other disorder, such as keratosis pilaris.

Whorled hair, in which multiple whorls are present, is probably a related disorder.⁷⁰¹ This phenomenon may be associated with anomalies in brain development.⁷⁰¹

Histopathology

In circle hair, there is no associated follicular abnormality or inflammatory component (Fig. 15.21).⁷⁰⁰

Keratotic plugs containing a coiled or broken hair are a characteristic feature of keratosis pilaris (see p. 498).⁶⁵⁷ Similar changes are seen in some cases of rolled hair, although keratotic follicular plugging is not always present.⁶⁹⁸

EXTRANEEOUS MATTER ON HAIR SHAFTS

Hair shafts may be colonized by fungi (tinea capitis and piedra), bacteria (trichomycosis axillaris), and the eggs (nits) of the lice causing pediculosis capitis.⁵³⁰ Casts resembling nits (hair casts, pseudo-nits) may occur in association with various scaly dermatoses of the scalp or as a rare, idiopathic phenomenon. Deposits such as lacquer, paint, and glue form another category of extraneous matter.

Figure 15.21 Circle hair. A hair shaft is coiled beneath the stratum corneum. Cross-sections of the coiled hair shaft are observed at both ends of the subcorneal space.

TINEA CAPITIS

In tinea capitis, fungal elements may be found on the surface of the hair shaft (ectothrix) or within the substance of the hair (endothrix).⁵³⁰ In both cases, the affected hairs are fragile and break near the skin surface.

PIEDRA

The condition known as piedra occurs in two forms, white piedra and black piedra.⁵³⁰ They are characterized by the formation of minute concretions on the affected hair (the Spanish word *piedra* means 'stone').

White piedra (*trichosporonosis*, *trichosporosis*)^{702,703} is a rare superficial infection of the terminal part of the hair caused by the yeast-like fungus *Trichosporon beigelii* (*cutaneum*). It occurs particularly in South America, areas of Europe, Japan, the Middle East, and the United States.^{704,705} There are numerous discrete or coalescing cream-colored nodules, just visible to the naked eye, forming sleeve-like concretions attached to the hair shaft.^{706,707} White piedra may affect hairs on the face, scalp, or scrotum.⁷⁰⁶ Fracture of the hair shaft may result. A synergistic coryneform bacterial infection is sometimes present.⁷⁰⁸

Black piedra, which is caused by the ascomycete *Piedraia hortae*, consists of gritty black nodules that are darker, firmer, and more adherent than those found in white piedra.⁷⁰⁷ Black piedra is prevalent in tropical climates. A case of black piedra due to *Trichosporon asahii* has been reported.⁷⁰⁹

The treatment of white piedra is an area of therapeutic frustration.⁷¹⁰ Shaving the hair is one recommended treatment, but this is not acceptable in some societies. Itraconazole has been used successfully in one series with a low failure rate but with some recurrences on cessation of treatment.⁷¹⁰ Antifungal shampoos have also been used alone⁷⁰⁸ or in combination with an oral azole antifungal agent.⁷¹¹

Histopathology

In *white piedra*, a potassium hydroxide preparation of a hair shows that the concretions are composed of numerous fungal arthrospores in

Figure 15.22 Trichomycosis. (A) Small pale nodules are attached to some of the hair shafts. (B) Microscopy of an involved hair shaft shows the attached extraneous matter.

compact masses encasing the hair shaft.⁷⁰⁷ In one case, white piedra spores were packed inside empty nits from an accompanying infestation with *Pediculus capitis*.⁷¹² In *black piedra*, the nodules are composed of brown hyphae with ovoid asci containing two to eight ascospores.⁷⁰⁷ The fungus shows strong keratinolytic activity with the capacity to destroy both the cuticle and the hair cortex.⁷¹³

TRICHOMYCOSIS AXILLARIS

In trichomycosis axillaris, there are tiny, cream to yellow nodules attached to axillary or pubic hair (Fig. 15.22).⁵³⁰ It is not a mycosis but, rather, the result of infection by a species of *Corynebacterium*.

PEDICULOSIS CAPITIS

Nits are small white to brown ovoid structures attached to the hair shaft.⁵³⁰ They are the eggs of the lice responsible for pediculosis capitis (see p. 774).

Histopathology

The egg lies to one side of the hair shaft, to which it is attached by a sheath that envelops both the shaft and the base of the egg.⁵³⁰

HAIR CASTS

Hair casts (peripilar casts, pseudo-nits) are firmish, yellow-white concretions, 3–7 mm long, ensheathing hairs and movable along them.⁷¹⁴ Two types of hair casts exist.^{715–719} The more common type (*parakeratotic hair cast*) is associated with various inflammatory scalp disorders, such as psoriasis, seborrheic dermatitis, and pityriasis capitis.⁷¹⁵ The second type (*peripilar keratin cast*), which is quite uncommon, occurs predominantly in female children without any underlying disease as a diffuse disorder of scalp hair.⁷¹⁶ Hair casts appear to be nothing more than portions of root sheath pulled out of the follicle by a hair shaft itself.⁷²⁰ Tight plaiting of the hair, leading to local scalp ischemia and consequent damage to the root sheaths of the follicle, may be responsible for the formation of hair casts.^{717–719} There is a strong association between traction alopecia and the development of hair casts;⁷²¹ in fact, dermoscopic identification of hair casts can be a clue to the diagnosis of traction alopecia.⁷²² Hair casts can also be a sign of pemphigus vulgaris of the scalp; acantholysis of outer root sheath epithelium has been suggested as a mechanism for hair cast development in this condition.⁷²³ A possible role for *P. acnes* has been proposed in a group of patients with seborrhea and nonscarring alopecia.⁷²⁴ Hair casts have also been associated with the use of a deodorant spray,⁷²⁵ usually causing small deposits (see later).

Histopathology^{720,726}

In both types of hair casts, the follicular openings contain parakeratotic keratinous material that breaks off at intervals to form the hair casts. In casts associated with parakeratotic disorders, it seems that only external sheath is present in the casts. In the uncommon peripilar casts, both inner and outer root sheaths are demonstrable on transverse section of the cast. Scanning electron microscopy has confirmed the presence of an inner, incomplete layer and an outer, thicker, but less compact layer.⁷²⁰ In a situation in which pemphigus vulgaris is a suspected diagnosis, direct immunofluorescence can be performed on plucked hairs to search for intercellular deposits of IgG in outer root sheath epithelium.⁷²⁷

DEPOSITS

Various substances may become adherent to hair shafts, causing an unusual appearance on microscopy.⁵³⁰ These include paint, hair spray, lacquer, and glue. Hair lacquer and gel can produce hair beads.⁷²⁸ Microscopy reveals that the deposits are not inherent parts of the hair shaft.⁵³⁰

ALOPECIAS

There are several hundred disease states or events that may precipitate abnormal hair loss. As a consequence, any etiological classification of the alopecias is invariably composed of long lists of causative factors.^{729,730} From a clinical standpoint, alopecias are usually divided into those that are patterned and those that diffusely involve the scalp. Further subclassification into scarring and nonscarring types is usually made. Scarring alopecias are almost invariably irreversible and are therefore of great clinical importance. Biopsies are not often taken from alopecias that are diffuse and nonscarring because the etiology is often apparent to the clinician or the alopecia is subclinical or not of cosmetic significance. Sellheyer and Bergfeld published a useful histopathological review of the alopecias.⁷³¹

A more useful approach for the dermatopathologist is a classification based on the mechanisms involved in the hair loss.⁷³² This has some shortcomings in that our knowledge of these mechanisms is not

Table 15.1 The histological features of alopecias on horizontal (transverse) sections

Infundibular level	
Lichenoid reaction (interfollicular epidermis)	Lupus erythematosus Lichen planopilaris (one-third of cases)
Lymphocytic infiltrate ± fibrosis	Lupus erythematosus* Lichen planopilaris* Idiopathic scarring alopecia
Neutrophilic infiltrate ± fibrosis (also lymphocytes and plasma cells)	Dissecting cellulitis of the scalp Folliculitis decalvans Acne keloidalis Infectious folliculitis
Miniature hair shafts	Androgenetic alopecia
Melanin casts	Trichotillomania/traumatic alopecia
Isthmus level	
Lymphocytic infiltrate ± fibrosis	Lupus erythematosus Lichen planopilaris Idiopathic scarring alopecia
Miniature bulbs and follicles of varying diameter (non-inflamed)	Androgenetic alopecia Alopecia areata (regrowth)
Miniature bulbs (inflamed ± apoptosis)	Alopecia areata Lupus erythematosus
Melanin casts/trichomalacia	Trichotillomania/traumatic alopecia
Hair bulb level	
Fibrous tract and reduced number of follicles	Alopecia areata Lupus erythematosus Lichen planus Androgenetic alopecia Idiopathic scarring alopecia Traction alopecia
Inflamed hair bulbs ('swarm of bees')	Active alopecia areata
'Torn' catagen follicles ± hemorrhage	Trichotillomania/traumatic alopecia

*Both have lichenoid features

complete, particularly in some of the congenital/hereditary alopecias. Furthermore, some of the early reports of this group lack histological descriptions of the skin and hair shafts. For this reason, the congenital/hereditary alopecias are considered together until further knowledge allows a more accurate subdivision based on the mechanism involved.

The histological diagnosis of the alopecias is best made from transverse (horizontal) as opposed to the traditional vertical section (Table 15.1). This view has been challenged by Böer and Hoene.⁷³³ Transverse (horizontal) sections allow all follicles in a biopsy to be visualized simultaneously.^{734–736} The diagnostic yield can be maximized if both vertical and transverse sections are utilized.⁷³⁷ This latter view has been championed by Elston *et al.*^{738,739} Either one alone (vertical or horizontal) may also be satisfactory.⁷⁴⁰

In horizontal sections of a 4-mm punch biopsy, approximately 33 terminal hairs will be present.⁷⁴¹ In the upper half of the dermis, hairs are arranged in follicular units containing 2–4 terminal hairs and often one or more vellus hairs. This subject is reviewed in the excellent monograph by Sperling.⁷⁴¹

The following classification of alopecias is used in the account that follows:

- Congenital/hereditary alopecias
- Premature catagen/telogen

- Premature telogen with anagen arrest
- Vellus follicle formation
- Anagen defluvium
- Scarring alopecias
- Hair shaft abnormalities (see p. 474).

Before discussing the various mechanisms of hair loss, brief mention is made of the normal hair cycle.

The normal hair cycle

The formation of hairs is a cyclical phenomenon that results from successive periods of growth, involution, and rest by hair follicles.^{742,743} In 2003, Stenn published a review of all aspects of the hair follicle and its molecular control.⁷⁴⁴ Other papers have also been published on this topic.⁷⁴⁵ The phase of active hair production is known as *anagen*. It lasts for a period of 2–6 years on the scalp, although the average duration is usually quoted as 1000 days.⁵³⁰ At any one time, 85–90% of the 100,000 hair follicles on the scalp are in the anagen phase. There is regional variation in the duration of anagen. For example, anagen lasts for approximately 1 year in the beard region, whereas its duration in the axilla and pubic region is only a few months.⁷⁴⁶ The length of a hair shaft is directly proportional to the length of the anagen phase.⁷⁴⁴

The involutionary stage, *catagen*, is quite short, lasting less than 2 weeks in each hair follicle on the scalp. There is very little regional variation in the duration of catagen, although in some animals this period may be as short as 24 hours. Approximately 1% of scalp follicles are in the catagen phase at any time.⁷³¹ In humans, the entry of follicles into catagen is a random process, in contrast to its synchronous onset in animals (molting). Seasonal factors, including temperature and light intensity, play some role in precipitating molting in certain animals. In other animals and in humans, the factors that normally precipitate catagen are not known.⁷⁴⁷ Recent studies have addressed this issue of the 'hair cycle clock'.^{748–750} The use of transgenic mice is providing valuable information.⁷⁵¹

Transforming growth factor- β (TGF- β) is expressed immediately before catagen and TNF- β during catagen.^{748,752} TGF- β plays an important role in keratinocyte apoptosis during catagen, and it facilitates shrinkage/contraction of the companion layer of the proximal and mid follicle.⁷⁵³ Glial cell line-derived neurotrophic factor is a member of the TGF- β superfamily.^{754,755} It too is differentially expressed in different stages of the hair follicle cycle.⁷⁵⁵ The levels of *c-myc*, *c-myb*, *bax*, and *c-jun* change immediately before or during early catagen, suggesting that they play a role in the induction of apoptosis.⁷⁴⁸ The oncogene *c-myc* has the ability to induce both cell growth and apoptosis, depending on environmental conditions.⁷⁵⁶ There are two clusters of *c-myc* expressing cells in anagen follicles.^{757,758} A reduction in *bcl-2* expression also occurs during catagen.⁷⁵⁹ The expression of heat shock protein-27 is weak in both catagen and telogen.⁷⁶⁰ These various cytokines may result from cyclic activation of the sonic hedgehog pathway. Catagen follows a set period of anagen that is presumably genetically determined in some way for each particular region. The mechanism by which hair follicles shorten during catagen was an enigma for a long time. It was in part attributed to the cessation of mitoses in the hair matrix and also to 'collapse', 'regression', 'disintegration', and 'involution' of the lower follicle.⁷⁶¹ It is now known that massive cell loss by apoptosis is the mechanism responsible for catagen involution.^{747,761,762} The apoptotic fragments are quickly phagocytosed by adjacent cells in the lower follicle and by macrophages.⁷⁴⁷ With progressive retraction of the follicle resulting from this cell loss, there is wrinkling and thickening of the fibrous root sheath.

The resting phase, *telogen*, lasts approximately 3 or 4 months. During this period, there is no active hair production.⁷⁴⁶ At any one time, approximately 10–15% of scalp follicles are in this phase. Often included as part of telogen is the lag phase (kenogen), the true resting period of the hair follicle.^{763,764} This is followed by regrowth of the hair

follicle and a new anagen phase. The telogen hair (club hair) is extruded and shed at this time. The cornified cells of the outer sheath in catagen, the cornified cells of the inner sheath, and the cornified cells of the hair combine to create the appearance of a club at the base of a telogen hair.⁷⁶⁵ Exogen and teloptosis are two terms that have been proposed for the process of shedding of the club hair.⁷⁶⁴ The club hair is not pushed from the follicle by the new anagen hair as once thought. There is a loss of adhesion between cells of the club hair and those of its epithelial envelope.⁷⁶⁴ Synchronized teloptosis (exogen) may account for the increased shedding in telogen effluvium.

Each stage of the hair cycle has a characteristic morphological appearance.⁷⁴²

Catagen follicles are characterized by loss of mitotic activity in the matrix and the cessation of pigment production by melanocytes in the hair bulb. Scattered apoptotic cells develop in the outer root sheath, an easily recognizable sign of catagen (Fig. 15.23).⁷⁵⁶ Some melanocytes also undergo apoptosis.⁷⁶⁶ The inner root sheath disappears, and there is progressive thickening and corrugation of the fibrous root sheath. The lower end of the follicle gradually retracts upwards with a trailing connective tissue streamer beneath it. It is possible that Langerhans

Figure 15.23 Early catagen follicle. Note the numerous apoptotic cells. (H&E)

cells play a role in the removal of melanin from the hair bulb in early catagen.⁷⁶⁷

Telogen follicles consist of a short protrusion of basaloid, undifferentiated cells below the epithelial sac that surrounds the club hair. This is situated not far below the entrance of the sebaceous duct. The telogen hair, if plucked, has a short, club-shaped root that lacks root sheaths and a keratogenous zone (Fig. 15.24). There is also depigmentation of the proximal part of the shaft.^{530,746} The transition from anagen to telogen is marked by downregulation of hair cortex-specific keratins and the appearance of hK14 in the epithelial sac to which the telogen hair fiber is anchored.⁷⁶⁸

Anagen growth recapitulates to some extent the changes present in the original development of the follicle.⁷⁶⁹ There is increased mitotic activity in the germinal cells at the base of the telogen follicle. This ball of cells extends downward, partly enclosing the dermal papilla.⁷⁷⁰ Both descend into the dermis along the path of the connective tissue streamer that formed during the previous catagen phase. The matrix cells of the new anagen bulb form a new inner root sheath and hair.⁷⁷⁰ Melanocytes lining the papillae form melanin again. Only anagen hairs show CD34 immunoreactivity with CD34⁺ cells located in the outer root sheath below the attachment zone of the arrector pili muscle.⁷⁷¹ CK15⁺ cells are located in the outer root sheath above the attachment zone.⁷⁷¹ CD1d is also expressed in anagen but not the other stages of the cycle.⁷⁷² Syndecan-1 is another substance that is differentially expressed during the hair cycle. This proteoglycan is strongly expressed in the anagen phase outer root sheath and in the dermal papilla, but expression diminishes with involution of the hair follicle.⁷⁷³ Plucked anagen hairs have long indented roots with intact inner and outer root sheaths and are fully pigmented.⁷⁴⁶ Slowly plucked anagen roots are bare and show ruffling of the cuticle over a special segment of the root: quickly plucked anagen roots are usually covered by various sheath remnants; hence, ruffling occurs only rarely.⁷⁷⁴

An attempt has been made to quantify the number of hairs lost daily. Based on the number of scalp hairs and the duration of anagen, a theoretical figure of 100 shed hairs per day is obtained. A more practical method of establishing a normal baseline of hairs shed and standardizing the process is the 60-second hair count.⁷⁷⁵ In this method, hair is combed with a standard comb for 60 seconds onto a towel or pillowcase and the hair is counted. The mean was 10.3 hairs in one study, but this figure may be artificially low because the hair was shampooed daily for the 3 days preceding the count.⁷⁷⁵

Figure 15.24 Telogen hairs with a short club-shaped root.

CONGENITAL/HEREDITARY ALOPECIAS

The rare alopecias of the congenital/hereditary clinical grouping are considered together because the mechanisms involved in the pathogenesis of the hair loss are not known for some of the conditions.⁷²⁴ Furthermore, biopsies have not been carried out on some of the entities listed, whereas in other instances the biopsy findings have not been consistent from one report to another. Several different clinical groups of congenital/hereditary alopecias (hypotrichosis) are usually recognized:^{557,776}

- Alopecias without associated defects
- Alopecias in association with ectodermal dysplasia
- Alopecias as a characteristic or inconstant feature of a named syndrome.

Alopecia or hypotrichosis occurs without any associated defect in alopecia universalis congenita, hereditary hypotrichosis (Marie-Unna type) and atrichia with papular lesions, and in keratosis pilaris atrophicans. These conditions are considered further here. Localized alopecia, possibly occurring as a nevus state, has been reported.⁷⁷⁷ Another localized form of alopecia, temporal triangular alopecia, involves the presence of vellus follicles and is discussed on page 491.

Alopecia is a characteristic feature of one subgroup of the ectodermal dysplasias, a heterogeneous group of congenital diseases involving the epidermis and at least one appendage. Absence or hypoplasia of hair follicles has been recorded in some of these rare syndromes,⁷⁷⁸ whereas in others no detailed studies have been made. The ectodermal dysplasias were discussed on page 316.

There is a long list of rare syndromes in which alopecia is a characteristic or inconstant feature.^{779,780} Skeletal abnormalities are present in one subgroup.^{557,781} These have been reviewed elsewhere.⁵⁵⁷ Little is known about the mechanism of the alopecia in this group. One entity, the Hallermann-Streiff syndrome, is discussed briefly later because something is known of its pathology.

ALOPECIA UNIVERSALIS CONGENITA

Alopecia universalis congenita (alopecia congenitalis, universal congenital alopecia; OMIM 203655) refers to cases of congenital alopecia without associated defects.^{557,782} It is a heterogeneous group. Hair loss occurs at birth or soon after in one subgroup with autosomal recessive inheritance, whereas in those with one form of autosomal dominant inheritance the hair is normal until mid childhood.^{783,784} The autosomal recessive form is linked to the human hairless gene (*HR*) at 8p21.2.^{785,786} Misdiagnosis as alopecia areata occurs.⁷⁸⁷ Another autosomal dominant form has been called **hypotrichosis simplex** (OMIM 146520).⁷⁸⁸ It is of early onset and without associated abnormalities. The scalp-limited form of this disorder is associated with mutations in the corneodesmosin (*CDSN*) gene, which has been mapped to chromosome 6p21.3.⁷⁸⁹⁻⁷⁹¹ Generalized hypotrichosis simplex is reportedly caused by mutations in two genes: adenomatosis polyposis coli downregulated 1 (*APCDD1*), which encodes a Wnt-1 inhibitor,^{792,793} and *RPL21*, a gene encoding ribosomal protein L21.⁷⁹⁴ Autosomal recessive transmission and a sporadic case have also been reported.⁷⁹⁵ The variant linked to a short anagen phase has now been reclassified as short anagen syndrome (see p. 484).⁷⁹⁶

Hypotrichosis with juvenile macular dystrophy (OMIM 601553) is a rare autosomal recessive disorder characterized by sparse and short hair and progressive degeneration of the retinal pigment epithelium leading to blindness by the second decade of life. It is due to a mutation in *CDH3*, a gene encoding P-cadherin, a major component of adherens junctions, located at 16q22.1.⁷⁹⁷

A related disorder, also due to a *CDH3* mutation, also causes ectodermal dysplasia, ectrodactyly, and macular dystrophy – EEM (OMIM 225280). Hypotrichosis and hypodontia are also present.⁷⁹⁷

Other hypotrichosis syndromes are an autosomal recessive localized form (OMIM 607903) due to a mutation in the desmoglein 4 (*DSG4*) gene on chromosome 18q12; another localized form (OMIM 611452) due to a mutation in the *P2RYS* gene at 13q14.12–q14.2;⁷⁹⁸ a total hypotrichosis caused by a mutation in the lipase H (*LIPH*) gene (OMIM 604379) on 3q27–q28;⁷⁹⁹ a hypotrichosis–lymphedema–telangiectasia (OMIM 607823) form due to a mutation in the *SOX18* gene at 20q13.33;⁸⁰⁰ and focal hypotrichosis occurring in Gomez–Lopez–Hernandez syndrome (OMIM 601853), also known as cerebello-trigeminal-dermal dysplasia.⁸⁰¹

Histopathology

The hair shafts in hypotrichosis simplex are slightly thinned, with no other characteristic abnormality;⁷⁹³ scanning electron microscopy fails to show significant structural abnormalities with the exception of slightly roughened cuticle edges.⁸⁰² Hair follicles are hypoplastic and reduced in number.⁵⁵⁷ In one report, they were described as being of vellus type.⁸⁰³ In one of the dominant forms, follicles are said to be normal in number initially, but they fail progressively to re-enter anagen.⁷⁷⁰ Small cystic remnants of the follicles lined by outer root sheath-like epithelium are often present in the dermis.⁸⁰⁴ In hypotrichosis with juvenile macular dystrophy, the appearances resemble chronic telogen effluvium.⁸⁰⁵

HEREDITARY HYPOTRICHOSIS

Hereditary hypotrichosis (Marie Unna type; OMIM 146550) presents with short, sparse hair at birth and hair growth in childhood that is coarse and wiry.⁸⁰⁶ There is progressive loss of hair resembling androgenetic alopecia, commencing during adolescence.⁵⁵⁷ It is an autosomal dominant condition associated with a defect in chromosomal region 8p21. One study mapped the gene to 8p21.3.⁸⁰⁷ This is close to, but distinct from, the human hairless gene (*HR*) responsible for atrichia with papular lesions (see later).⁸⁰⁸⁻⁸¹⁰ The condition is now known to be caused by a single-base mutation, c.3G > A (p.M1I), in the *U2HR* gene, an inhibitory upstream open reading frame in the 5'-untranslated region of the *HR* gene.⁸¹¹ This mutation has been found in several unrelated families from different ethnic backgrounds, and it was actually found in the family from the original 1925 report of the condition by Marie Unna.⁸¹² However, there appears to be genetic heterogeneity,⁸¹³ and a study by Zhang *et al.* identified a missense mutation in the *EPS8L3* gene in a family from the Anhui Province in China. The *EPS8* gene encodes a family of proteins involved in EGF-R signaling, important in the initiation of hair growth.⁸¹⁴

The association of Marie Unna hypotrichosis with onycholysis and cleft lip/palate has been given the OMIM number of 609250. It is not related to the gene that causes Marie Unna hypotrichosis.

Histopathology

There are no specific features apart from a mild to moderate perifollicular inflammatory reaction, although progressive destruction of hair follicles is the probable mechanism.^{557,815} Follicles are reduced in number. Milia, mild fibrosis, and perifollicular granulomas have been recorded.^{557,815} Hair shaft examination has shown trichorrhexis nodosa, trichoschisis, and pigment clumping.⁸¹⁶

ATRICHIA WITH PAPULAR LESIONS

Atrichia with papular lesions (OMIM 209500) is a rare disorder in which progressive shedding of scalp and body hair occurs in the first

few months of life.^{817–820} The eyelashes are typically spared. Numerous small, milia-like cysts develop on the face, neck, scalp, and extremities in childhood and early adult life.⁸²¹ It is an autosomal recessive condition in which mutations occur in the human hairless gene (*HR*), a putative single zinc finger transcription factor protein that has been mapped to chromosome 8p21.2.^{785,822,823} Numerous mutations have been described.^{824–827} Compound heterozygosity has also been reported.⁸²⁸ Mutations in this gene are also responsible for alopecia congenitalis (universal congenital alopecia), which differs by having no papular lesions (discussed previously).^{785,829}

Atrichia with papules also occurs in the clinical setting of vitamin D-dependent rickets type IIA (OMIM 277440), resulting from mutations in the vitamin D receptor (*VDR*) gene on chromosome 12q13.1.^{830–833} The clinical findings of the two types are strikingly similar.

Histopathology⁸¹⁷

A few vellus follicles can be identified in the scalp, associated with chronic and granulomatous inflammation around the infundibular and isthmic zones but not the hair bulbs.⁸³⁴ The small follicular cysts resemble milia. They contain keratinous material, which is sometimes calcified, but there are no vellus hairs in the lumen. Scattered foreign body giant cells may be present around some of the cysts. In the scalp, the infundibulum of the follicle is normally developed, although it often contains a keratin plug. There is a lack of development of the germinal end of the follicle, with no shaft formation.⁸³⁵ A histological comparison of alopecias associated with vitamin D-dependent rickets and hairless gene mutations found striking similarities.⁸⁰⁴

KERATOSIS PILARIS ATROPHICANS

Keratosis pilaris atrophicans refers to a group of clinically related syndromes in which inflammatory keratosis pilaris leads to atrophic scarring (see p. 499). This condition is mentioned here because it is regarded as a congenital follicular dystrophy.

HALLERMANN–STREIFF SYNDROME

The Hallermann–Streiff syndrome (mandibulo-oculofacial dyscephaly; OMIM 234100) is a branchial arch syndrome that combines a characteristic bird-like facies with ocular abnormalities and alopecia, which may have an unusual sutural distribution on the scalp.^{836,837} Atrophic patches of skin, which may be limited to the areas of alopecia, also occur.⁸³⁶ Most cases appear to occur as new mutations.⁷⁷⁰

The **trichorhinophalangeal syndrome** (OMIM 190350) is a rare autosomal disorder with sparse and slow-growing hair, facial dysmorphism, and bone deformities.⁸³⁸ It is due to mutations in the *TRPS1* gene on chromosome 8q24. It encodes a zinc finger transcription factor.⁸³⁹

Histopathology

Very little is known about the histological characteristics of the alopecia, although the atrophic areas are composed of loosely woven collagen.⁷⁷⁰ The hair shafts show some cuticular weathering on scanning electron microscopy.⁸³⁶ Circumferential grooving of the shaft has also been noted in some cases.⁸⁴⁰ Miniaturization of hair follicles has been described in the alopecia of trichorhinophalangeal syndrome.⁸⁴¹ Expression of *TRPS1* was found to be markedly reduced in epidermis and outer root sheaths of hair follicles compared to that in a normal subject.⁸⁴¹

SHORT ANAGEN SYNDROME

This recently described anomaly is characterized by ‘hair that never needs cutting’. It has probably been underreported.⁷⁹⁶ There is short, fine scalp hair with normal body hair and eyelashes.⁸⁴² Only 24% of hairs were in anagen in one hair pull study.⁸⁴² A biopsy, with vertical and not horizontal sections, appeared unremarkable. Thai and Sinclair reported a case with persistent synchronized scalp hair growth associated with short anagen duration.⁸⁴³ A patient with two localized areas of short anagen (*‘short anagen hair nevus’*) responded to treatment with 5% topical minoxidil.⁸⁴⁴ Another patient responded to combination therapy with topical minoxidil and systemic cyclosporin therapy.⁸⁴⁵

Histopathology

Biopsy has shown mild perifollicular lymphocytic inflammation and, in horizontal sections, an increased telogen:anagen ratio.⁸⁴⁵ Another study reported a normal number of vellus and intermediate follicles (follicles of intermediate size between vellus and terminal hair follicles), with perifollicular fibroplasia around intermediate follicles and infundibular trichomalacia.⁸⁴⁶

PREMATURE CATAGEN/TELOGEN

At any one time, approximately 10–15% of the hair follicles of the scalp are in the resting (telogen) phase and, because of its shorter duration, only a small number of follicles are in the preceding involutionary stage of catagen. In certain circumstances, an abnormal number of hair follicles are in the telogen phase. This results from the premature termination of anagen.⁸⁴⁷ After a latent period of approximately 3 months from the onset of catagen/telogen, club hairs are lost, leading to thinning of the hair.⁸⁴⁷ It is surprising how much hair can be lost before this thinning becomes noticeable.⁸⁴⁷ A cyclical increase in telogen hairs has been reported in patients with severe dandruff in whom increased hair shedding and a slowly progressive alopecia may develop.⁸⁴⁸

Numerous telogen follicles are found in telogen effluvium (see later), a condition that results from various stressful circumstances and from some drugs, such as heparin.⁸⁴⁷ Catagen hairs are not usually found because such conditions are not biopsied until the hair loss becomes noticeable, approximately 3 months after the onset.

In trichotillomania (see later) and certain traumatic alopecias, the insult is usually continuous and, accordingly, catagen follicles are seen in addition to telogen ones. Catagen follicles are sometimes prominent at the rapidly advancing edge of a patch of alopecia areata.

In summary, catagen follicles are prominent in trichotillomania and related traumatic alopecias resulting from traction associated with hairstyles and the like. They are often seen at the edge of a patch of alopecia areata. Telogen follicles are prominent in telogen effluvium, in alopecia areata, and in a rare disorder with its onset in childhood – familial focal alopecia.⁸⁴⁹ In this latter condition, there is telogen arrest with prolonged persistence of telogen follicles, in contrast to the transient nature of the process in telogen effluvium.⁸⁴⁹

TRICHOTILLOMANIA AND TRAUMATIC ALOPECIA

Trichotillomania is a rare form of alopecia resulting from the deliberate, although at times unconscious, avulsion of hairs by patients who may be under psychosocial stress.^{850,851} In adults, it is more common in women; in children, there has been no sex predilection in some series. In children, eating the plucked hair may lead to the formation of trichobezoar (hair balls).⁸⁵² It has been claimed that the term

‘trichotillomania’ is outdated, pejorative, and offensive to patients.⁸⁵³ The term ‘neuromechanical alopecia’ has been suggested as a replacement.⁸⁵³

Although the crown and occipital scalp are primarily affected, other areas of the scalp, as well as the eyebrows, trunk, and pubic areas,⁸⁵⁴ may also be involved. Isolated involvement of the eyebrows and eyelashes has been reported.^{855,856} Similar features can result from traction of hair associated with hairstyles and from prolonged pressure.⁸⁵⁷ Pressure appears to be involved in the occipital alopecia that occurs in children and some adults after surgery of prolonged duration.^{858,859} The term ‘traumatic alopecia’ can be applied to such cases, including trichotillomania.^{860,861} Clinical differentiation from alopecia areata can be difficult.

A related disorder involving the nails is called **onychotillomania**, in which patients neurotically pick or injure their nails until they are permanently altered.⁸⁶²

If trauma (e.g., traction) is repeated, prolonged, and severe, then additional features, including scarring, will develop. This is best called traction alopecia with scarring, but it is also known as ‘hot comb’ alopecia and follicular degeneration syndrome (see p. 495).⁸⁶³

The management of patients with trichotillomania involves psychiatric and support services beyond the scope of this book. Guidelines for the management of trichotillomania were published in 2002.⁸⁶⁴ Placing an occlusive bandage over the site can allow hair regrowth in the protected site and reinforce an understanding of the role of trauma in patients with this condition.⁸⁶⁵ Traction alopecia is best managed by advice to patients on the underlying mechanism of their alopecia.

Histopathology^{731,866–870}

The histological features are characteristic, but not all of the recognized features are present in every biopsy. There is a greater chance of observing them if multiple sections are examined. Horizontal sections also enhance the diagnostic rate, although most studies have been done on vertical sections.⁷⁴¹ The two most specific features are the presence of increased numbers of catagen hairs (**Fig. 15.25A**), associated usually with the presence of early and late anagen hairs, and the presence of empty hair ducts.⁸⁶⁴ Bergfeld and colleagues believe that trichomalacia and pigmented casts (see later) are the major diagnostic criteria.⁸⁷¹ Other changes include dilated follicular infundibula that may contain melanin casts and keratin plugs, clefts around the lower end of hair follicles, distortion of the hair bulb with dissociation of cells in the hair matrix, the release of melanin pigment within the papilla and surrounding connective tissue sheaths, traumatized connective tissue sheaths, small areas of dermal hemorrhage, and empty spaces in the sebaceous glands (**Fig. 15.25B**).⁸⁶⁷ The pigment casts may not be the result of hair manipulation but, rather, a reflection of the sudden termination of the anagen phase of the hair cycle.⁸⁵⁹ Sometimes splitting of the hair shaft in a vertical orientation occurs with proteinaceous material and erythrocytes in this split. This has been called the ‘hamburger bun sign’.⁸⁷² Sometimes there is even extrusion of sebaceous lobules. Only a very sparse inflammatory infiltrate is present.

Differential diagnosis

Trichotillomania shares some microscopic features with alopecia areata, including catagen follicles, but trichomalacia and pigment casts are features favoring the former disorder.

Dermoscopy (trichoscopy) can also be helpful in the distinction between these two disorders. Fractured hair shafts favor trichotillomania, whereas exclamation mark hairs are typical for alopecia areata. Yellow dots (distension of follicular infundibula with keratinous material and serum) that may or may not contain black dots (cadaveric hairs typically seen in alopecia areata) can be seen in either condition.⁸⁷³ Other trichoscopic features characteristic for this disorder have been described; these include flame hairs, the ‘v-sign’, coiled hairs, and hair powder.⁸⁷⁴

Figure 15.25 Trichotillomania. (A) A catagen/telogen follicle is present (arrow). A melanin cast and trichomalacia can also be observed. **(B)** Melanin casts and keratin plugs are present in the dilated follicular infundibula. (H&E × 2)

TELOGEN EFFLUVIUM

Telogen effluvium is an abnormality of hair cycling that results in excessive loss of telogen hairs. It has been regarded as a syndrome and as a nonspecific reaction pattern rather than as a disease sui generis.^{847,875–877} It is nevertheless a useful term to apply to those cases of diffuse hair

loss in which various stressful circumstances precipitate the premature termination of anagen. It is one of the most common causes of diffuse hair loss.⁸⁷⁸ Telogen effluvium can follow febrile illness, parturition, systemic illnesses, chronic infections (including HIV infection),⁸⁷⁹ allergic contact dermatitis of the scalp,⁸⁸⁰ air travelers' 'jet lag', psychogenic illnesses, 'crash diets', iron deficiency,^{881,882} and sudden severe stress.⁸⁸³ It may also be associated with an internal cancer,⁷³² cytotoxic drugs,⁸⁸⁴ and the eosinophilia–myalgia syndrome.⁸⁸⁵ Loss of hair in the newborn is a physiological example of this process.⁸⁴⁷ Exceptionally, drugs such as heparin, clofibrate, gentamicin, niacin (nicotinic acid), nitrofurantoin, salicylates, oral contraceptives, anticonvulsants, pramipexole,⁸⁸⁶ excess vitamin A, and the antihypertensive agent minoxidil⁸⁸⁷ have been implicated in the etiology of telogen effluvium.^{735,888,889} Headington defined five different functional types of telogen effluvium.⁸⁸⁹

Telogen effluvium presents as a diffuse thinning of the scalp hair, although the hair loss is not always obvious clinically. Hair loss usually occurs approximately 3 months after the precipitative event. Sometimes this hair loss unmasks small areas of alopecia, of other causes, that had previously gone unnoticed.

In **chronic telogen effluvium** (defined as shedding that persists beyond 6 months), there is hair shedding of abrupt onset followed by a fluctuating course in which there is diffuse thinning all over the scalp, frequently accompanied by bitemporal recession.^{883,890} There is no frontoparietal hair loss, and these women characteristically present with a full, thick head of hair.⁸⁹¹ It is more common in postmenopausal women,⁸⁹² but it has been seen in men.⁸⁹³ It must be distinguished from female pattern hair loss, which often has overlapping features.^{894,895} Both conditions may have trichodynia.⁸⁹⁶ Hair shedding in this condition appears to be self-limiting.

Histopathology

A biopsy of the affected scalp will show a proportionately greater number of normal telogen follicles than usual (Fig. 15.26).⁷³¹ The total number of hair follicles is normal. There is no inflammation in the dermis. An examination of plucked hairs will reveal telogen counts greater than 25%.

In horizontal sections of *chronic* telogen effluvium, the terminal:vellus-like hair ratio (T:V) in one study was 9:1 compared to 1.9:1 in androgenetic alopecia.⁸⁹⁰ At the mid-isthmus level, a T:V of less than 4:1 is considered diagnostic of female pattern hair loss, whereas a ratio greater than 8:1 indicates chronic telogen effluvium.⁸⁹¹ The differentiation of chronic telogen effluvium from female pattern hair loss is considerably enhanced by the use of triple horizontal biopsies versus a single horizontal biopsy.⁸⁹⁷ Using a computer simulation, Gilmore and Sinclair found evidence that chronic telogen effluvium may result from a reduced variance in anagen duration.⁸⁹⁸ Inflammation is also more common in androgenetic alopecia than in chronic telogen effluvium.⁸⁹⁰

PREMATURE TELOGEN WITH ANAGEN ARREST

Alopecia areata is the only type of hair loss in which the mechanism of premature telogen with anagen arrest applies. At the expanding edge, follicles in late catagen and telogen are characteristic findings, although in older lesions follicles in an arrested anagen phase are also present.

ALOPECIA AREATA

Alopecia areata (OMIM 104000) is a relatively common condition affecting individuals of any age but particularly those between the ages

Figure 15.26 Telogen effluvium. There is an increase in the number of normal telogen follicles. (H&E)

of 15 and 40 years.^{899–902} Its incidence is 0.1–0.2%,⁹⁰³ and the lifetime risk is approximately 2%. More than 4.5 million people in the United States are affected.⁹⁰⁴ Although mild cases may escape clinical detection, alopecia areata usually has a sudden onset with the development of one or more discrete, asymptomatic patches of nonscarring hair loss on the scalp.⁹⁰⁵ Exclamation mark hairs are found near the advancing margins.⁹⁰⁵ The clinical course is variable.⁹⁰⁶ There may be spontaneous remission, sometimes followed by exacerbations, or there may be relentless progression to involve the entire scalp (alopecia totalis) and, uncommonly, all body hair (alopecia universalis).^{907,908} Progression to alopecia totalis is more likely in children.^{909–911} In one study, 7% of patients with alopecia areata progressed to alopecia totalis or universalis.⁹¹² HLA-DR11, HLA-DR4, and HLA-DQ7 are significantly increased in frequency in patients with alopecia totalis/alopecia universalis in contrast to patients with patchy alopecia areata.^{913,914} Alopecia universalis may be a manifestation of the immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) syndrome (OMIM 304790) due to a mutation in the *FOXP3* gene at Xp11.23–q13.3.⁹¹⁵ It also occurs as a manifestation of Satoyoshi syndrome (OMIM 600705), in which there are intermittent painful muscle spasms and malabsorption. Other HLA profiles may be increased in some ethnic groups.⁹¹⁶

A family history of alopecia areata is present in 8–50% of affected individuals.^{899,909,917–922} Inheritance is polygenic,⁹²³ but there appears to be an association with HLA class II genes.^{822,924–926} More specific genetic associations have now been reported. It has been associated with a genetic variant in the protein tyrosine phosphatase nonreceptor 22 (*PTPN22*) gene.⁹²⁷ In another study, four susceptibility loci were found on chromosomes 6, 10, 16, and 18.⁹⁰⁴ The locus on chromosome 6 was in the region of the MHC locus.⁹⁰⁴ The chromosome 16 locus has been given an OMIM number of 610753, a gene map locus of 16q11–q22, and the title of alopecia areata type 2. There is a 55% concordance

rate in identical twins.⁹²⁸ Congenital alopecia areata is exceedingly rare.^{929,930}

Regeneration is heralded by the development of fine white or tan hair.⁹⁰⁵ Most often, the depigmented hair regrowth lasts one hair cycle, but persistent depigmented hair does occur.⁹³¹ In one such case, only pigmented hairs were lost in the initial hair loss phase leading to completely white hair after treatment and regrowth.⁹³² In another case, graying hairs were spared.⁹³³

There are conflicting data on the clinical associations of alopecia areata. Many reports have documented an increased incidence of autoimmune diseases such as Hashimoto's thyroiditis, Addison's disease, atopic dermatitis,⁹³⁴ idiopathic primary hypophysitis,⁹³⁵ thrombocytopenia,⁹³⁶ vitiligo,⁹³⁷ and lupus erythematosus, but not others.^{905,907,938} Children with alopecia areata have an increased family history of autoimmunity.⁹³⁹ Autoantibodies to various thyroid antigens,⁹⁴⁰⁻⁹⁴² gastric parietal cells,⁹¹⁷ and smooth muscle⁹⁴³ have been reported,⁹⁴⁴ although not all of these findings have been confirmed by others.⁹⁴⁵ There are also conflicting results on the various cell-mediated functions in alopecia areata, but this may in part reflect the different techniques that have been used and the heterogeneous nature of this condition.^{942,946} Other clinical associations have included atopic states,^{920,947} Down syndrome,^{948,949} Turner's syndrome,⁹⁵⁰ the use of rifampin (rifampicin),⁹⁵¹ efalizumab,⁹⁵² adalimumab,⁹⁵³ infliximab,^{952,954} cyclosporine,⁹⁵⁵ etanercept,⁹⁵⁶ and IFN- α ,⁹⁵⁷ hypomagnesemia,⁹⁵⁸ HIV infection,⁹¹⁰ psychiatric co-morbidity,⁹⁵⁹ CMV infection,⁹²⁸ Epstein-Barr virus infection,⁹⁶⁰ pili annulati,⁹⁶¹ the regression of cutaneous melanoma,⁹⁶² the sparing of areas with psoriasis⁹⁶³ and with a congenital nevus,⁹⁶⁴ and following vasectomy.⁹⁶⁵ Various nail changes have been reported in 10-25% of patients,^{921,966} with frequencies in some studies as high as 66%.⁹³⁴ Pitting is the most common nail change, but others include trachyonychia, Beau's lines, and onychorrhexis. Reduced sweating has also been documented.⁹⁶⁷ Rarely, it may masquerade as other alopecias, such as trichotillomania⁸⁵⁶ and frontal fibrosing alopecia.⁹⁶⁸ Migratory poliosis may be a forme fruste of alopecia areata.⁹⁶⁹ Although eyebrow loss may occur in alopecia areata, diffuse eyebrow loss can occur in a familial setting in the absence of scalp hair loss.⁹⁷⁰

Alopecia areata incognita is a variant of alopecia areata characterized by acute diffuse shedding of telogen hairs in the absence of typical patches.⁹⁷¹ Clinically, it has the features of telogen effluvium. Scalp dermoscopy shows characteristic round or polycyclic yellow dots and numerous short regrowing hairs.⁹⁷¹ Fine depigmented hair may be present.⁹⁷²

Pathogenesis

Although the pathogenesis of alopecia areata is not understood, the evidence for an immunological basis comes from five sources:^{907,973,974} the clinical association of other autoimmune diseases, the presence in some patients of circulating antibodies directed to a range of hair follicle antigens,⁹⁷⁵⁻⁹⁷⁷ altered cellular immune functions,^{978,979} the favorable effects of treatment with synthetic immunomodulators,^{980,981} and the histopathological finding of activated and autoreactive T cells and HLA-DR expression^{982,983} in the vicinity of the hair bulb.^{984,985} Antibodies against hair follicles are present in patients with alopecia totalis occurring in association with the autoimmune polyendocrine syndrome type I (OMIM 240300).⁹⁸⁶ This syndrome is due to mutations in the autoimmune regulator (*AIRE*) gene on chromosome 21q22.3. Not only antibodies but also alopecia areata are present in this syndrome.⁹⁸⁷ Alopecia areata has developed in a leukemic patient after allogeneic bone marrow transplantation from an affected sibling.⁹⁸⁸ The initial stages of the disease involve T lymphocytes and dendritic cells that are CD1a and CD36 positive.⁹⁸⁹⁻⁹⁹¹ Serum chemokines, such as MIG (monokine induced by IFN- γ) and RANTES, are increased in alopecia areata and are useful markers of disease activity.⁹⁹² The lymphocytes appear to be of oligoclonal origin.⁹⁹³ One study suggests that CD8⁺

cells, even though they are less frequent than CD4⁺ cells in the infiltrate, play an important pathogenic role, with the CD4⁺ cells in their classic helper/supporter role.⁹⁹⁴⁻⁹⁹⁹ Both CD4⁺ and CD8⁺ lymphocytes express cutaneous lymphocyte-associated antigen (CLA).¹⁰⁰⁰ The levels of IL-2R, IL-5, and IL-6 are significantly higher in cultured blood monocytes from patients with patchy alopecia areata than in controls.¹⁰⁰¹ Treatment with diphencyprone leads to an increase in CD8⁺ cells and a significant decrease in CD4⁺ cells.¹⁰⁰² IL-4 production may be impaired.¹⁰⁰³ Adhesion molecule receptors are involved in the initial trafficking of leukocytes into the dermis.⁹⁸⁹ The effect of psychological factors, which play an important role in some patients with alopecia areata, may be mediated by neuropeptide substance P, which is increased in nerve fibers in areas of hair loss.¹⁰⁰⁴

The basic disturbance is the premature entry of anagen follicles into telogen, although some follicles survive for a time in a dystrophic anagen state.¹⁰⁰⁵

The term 'nanogen' has been proposed for the morphologically distorted telogen follicle that is produced in alopecia areata.¹⁰⁰⁶ Follicles may re-enter anagen, but growth appears to be halted in anagen stages III and IV.¹⁰⁰⁷ Interestingly, follicles producing nonpigmented hair are less susceptible to premature telogen.⁸⁹⁹ Cell deletion by apoptosis, probably cell mediated, is the mechanism by which premature catagen and telogen come about. Apoptosis may also play a role in the anagen arrest that occurs.¹⁰⁰⁷ Graft experiments suggest that hair growth ability *in situ* is normal and the causation is mediated humorally.¹⁰⁰⁸

The prognosis of alopecia areata is difficult to predict. Severity of the disease at the time of first consultation is an important prognostic factor. The most important adverse prognostic factors are the extent of hair loss presentation (e.g., alopecia totalis or universalis) or the ophiasis pattern of hair loss: band-like hair loss in the parieto-temporo-occipital region.⁹³⁴ Response to topical immunotherapy may be associated with a better prognosis.¹⁰⁰⁹ In children, the prognosis is worse.¹⁰⁰⁹

For patchy alopecia, treatments include topical and/or intralesional corticosteroids, diphencyprone, and topical minoxidil 5%.^{903,920,1002} For more extensive disease, topical dinitrochlorobenzene (DNCB), squaric acid,⁹²⁰ PUVA therapy, weekly oral or subcutaneous methotrexate, with or without low-dose (oral) corticosteroids, sulfasalazine, and oral or pulse intravenous corticosteroids have been used.

Histopathology¹⁰⁰⁵

The appearances vary according to the duration of the process at the biopsy site (Fig. 15.27). At the expanding edge, the majority of the follicles are in late catagen and telogen. A few anagen follicles are in the subcutis while small (miniaturized) mid-dermal ones may also be seen. The larger anagen follicles show a peribulbar infiltrate of lymphocytes (likened to a swarm of bees) and macrophages and sometimes a few eosinophils and plasma cells (Fig. 15.28).¹⁰⁰⁵ They are found around terminal hairs in early stages and around miniaturized anagen hairs in repeated episodes.¹⁰¹⁰ Peribulbar inflammation tends to subside as affected follicles enter the telogen phase, but occasionally a few inflammatory cells can still be found around telogen follicles.⁷⁴¹ It should be stressed that an inflammatory infiltrate is not always found in alopecia areata, particularly in chronic disease; in that situation, horizontal sections are recommended for accurate diagnosis because they allow for assessments of follicle density, diameter, and cyclical changes.¹⁰¹¹ Eosinophils were present in the fibrous tracts and near hair bulbs in 38 of 71 cases in one study¹⁰¹² and in 11 of 51 cases in another.¹⁰¹³ Mast cells are common in the fibrous tracts, but they can also be found in androgenetic alopecia. There is also exocytosis of inflammatory cells into the bulbar epithelium.¹⁰¹⁴ The majority of the lymphocytes are small and mature.¹⁰¹⁵ Some Langerhans cells are also present. The small anagen follicles show a disproportionate reduction in the size of the epithelial matrix relative to that of the dermal papilla. In another study of the early changes in terminal anagen hair follicles,

Figure 15.27 (A) Alopecia areata. This is a late-stage lesion with a complete loss of follicles. **(B)** A fibrous tract extends along the site of the previous follicle. A small, early anagen follicle is above. A few lymphocytes are also present. (H&E)

peribulbar lymphocytes were seen associated with destruction of the upper bulb up to the keratogenous zone.¹⁰¹⁶ There were clefts between keratinocytes that had a ‘crumbled’ appearance. The hair matrix was initially intact, but eventually the papilla was no longer embraced by the matrical epithelium.¹⁰¹⁶ By this stage, the bulb showed advanced shortening with numerous apoptotic cells, indicative of catagen hairs. Kamino and colleagues stated that although lymphocytes extend up to the bulge region of the follicle, they do not target stem cells as in lichen planopilaris.¹⁰¹⁷

In established cases and in alopecia totalis, there are many telogen follicles and some small anagen follicles with mid-dermal bulbs.¹⁰⁰⁵ There are a decreased number of terminal anagen hairs. The anagen:telogen ratio is variable. Although routine sections give the impression of marked follicle loss because of the absence of follicles in the subcutis, the use of transverse sections allows a better assessment of follicle density.⁷³⁴ A quantitative study, using horizontal sections, found an average of 40 hairs in a 4-mm biopsy of normal scalp but only 27 in alopecia areata.¹⁰¹⁸ The study also showed an increase in vellus follicles and also of telogen follicles in alopecia areata.¹⁰¹⁸ This has prognostic significance because it indicates that normal regrowth of hair is theoretically possible in these circumstances.⁷³⁴ There is only

a mild peribulbar inflammatory cell infiltrate around these small anagen follicles. Occasional apoptotic cells and mitoses can be seen. Empty infundibula are common. Pigment incontinence is seen around the site of the previously deeper hair bulbs. Atrophy of sebaceous glands is seen sometimes in long-standing cases.¹⁰¹⁹ Incidental follicular mucinosis has been reported.¹⁰²⁰ Dermal mucin is a rare finding. It may signify underlying lupus erythematosus.¹⁰²¹

In regenerating areas, the number of melanocytes and the degree of pigmentation of the cells in the hair bulb are much less than in the normal pigmented follicle.^{1005,1007}

In all stages, a nonsclerotic fibrous tract extends along the site of the previous follicle into the subcutis. This stela represents a collapsed fibrous root sheath. This fibrous tract contains a few small vessels and small deposits of melanin. In cases of long standing, there is widespread damage and fibrosis to the follicular sheath structures. There may be only a few lymphocytes and macrophages at the site of the previous hair bulb. There are no Arão-Perkins elastic bodies along this connective tissue tract, such as are seen in male pattern (androgenetic) alopecia.¹⁰²²

Assessments have been made of scalp biopsies from patients with long-standing alopecia totalis and universalis who did not respond to

Figure 15.28 Alopecia areata. Lymphocytes surround the bulbar region, giving the characteristic 'swarm of bees' sign. (H&E)

sensitizing therapies.⁹⁶⁸ From a pathological standpoint, nonresponder patients constitute a heterogeneous population, with early regrowth, telogen, scarring, and early anagen arrest patterns present in different patients.¹⁰¹⁹

Kossard presented a case with miniaturized follicles and a heavy (nonlichenoid) lymphocytic infiltrate at the level of the stem-cell rich region near the entry of the sebaceous duct.¹⁰²³ He considered that it might be a variant of alopecia areata and used the term 'diffuse alopecia with stem cell folliculitis'.¹⁰²³ Stem cell apoptosis has also been seen in HIV-associated alopecia.¹⁰²⁴ Follicular mucinosis has been seen in a case of diffuse alopecia of the scalp resembling alopecia areata.¹⁰²⁵

Immunofluorescence shows deposits of C3 and occasionally of IgG and IgM along the basement zone of the inferior segment of hair follicles.¹⁰²⁶ Careful ultrastructural studies are needed to assess the role of lymphocyte-mediated apoptosis in the pathogenesis of this disease.

Electron microscopy¹⁰²⁷

Apoptosis has been seen not only in the outer root sheath of catagen follicles but also in matrix keratinocytes and anagen hair bulbs. Dark cell transformation is also present. Ultrastructural studies of exclamation mark hairs show asymmetrical cortical disintegration below the

frayed tip.¹⁰²⁸ Cells in the dermal papilla show signs of injury, and there are abnormal amounts of pigment.¹⁰²⁹

Differential diagnosis

Individual features of alopecia areata can mimic those of several forms of alopecia. Androgenetic alopecia also features increased numbers of diminutive follicles, acellular fibrous stela, and increased telogen follicles, although the telogen counts are only slightly increased. Unlike androgenetic alopecia, in which inflammation, when present, is found around the superficial portions of follicular units, alopecia areata (except in late stages) often shows inflammation and pigment deposition within the fibrous stela as well as peribulbar inflammation. Trichotillomania also shows trichomalacia, increased catagen follicles, and pigment deposition within follicles. However, that disorder lacks the inflammatory changes, nanogen follicles, and staged sequence of events of alopecia areata, and of course the clinical history is quite different. Chronic telogen effluvium has normal total follicle counts, in contrast to the decreased counts in alopecia areata.¹⁰¹¹ Although both syphilitic alopecia and alopecia areata have lymphocytic infiltrates around the lower portions of follicular units, small anagen follicles, and increased catagen/telogen follicles, plasma cells are usually present in the infiltrates of syphilitic alopecia and typically absent in alopecia areata.

VELLUS FOLLICLE FORMATION

This group of alopecias is characterized by the presence of small vellus follicles in the dermis. In androgenetic alopecia (common baldness), which is the most important member of this group, an early biopsy may only show a progressive diminution in the size of follicles that are not truly vellus. In established lesions, typical vellus follicles will be seen. Vellus follicles are also a feature of temporal triangular alopecia, but this presumably represents the development of vellus follicles in the affected site *ab initio* rather than the progressive reversion of terminal hair follicles to vellus follicles.

ANDROGENETIC ALOPECIA

Androgenetic alopecia (common baldness, androgenic alopecia) is a physiological event that may commence in males soon after puberty.^{1030,1031} It occurs less often in females, and its onset is a decade or so later than in males. It has been said to affect at least 50% of men by the age of 50 years¹⁰³² and 80% at the age of 70 years,¹⁰³³ whereas it affects approximately 40% of women aged 70 years or older.¹⁰³⁴ Although often considered an adult disease, androgenetic alopecia is also the most common cause of hair loss in adolescents, with a male:female ratio of 2:1; it can be a sign of endocrinologic dysfunction in some instances.¹⁰³⁵ The hair loss is more obvious in men. Clinically, there is progressive replacement of terminal hairs by fine, virtually unpigmented vellus hairs, with hair loss in distinct geographical areas of the scalp.¹⁰³⁶ Hair diameter diversity is an important clinical sign that reflects the underlying follicular miniaturization characteristic of this condition.¹⁰³⁷ Increased shedding of hairs is usually noted.¹⁰³⁰ In females, there may be features of hyperandrogenism, such as hirsutism and acne.¹⁰³⁸ However, it has been reported in a female with hypopituitarism, indicating that it is not always androgen dependent.¹⁰³⁹ Cigarette smoking may predispose to androgenetic alopecia,¹⁰⁴⁰ although this was not confirmed in another study.¹⁰³³

In males, the hair loss is patterned and involves the frontal, central, and temporal regions. Uncommonly, there is sparing of the frontoparietal hairline in men.¹⁰⁴¹ Various categories of male baldness have been defined, based on which of the previously discussed anatomic areas are involved.^{1030,1042} Hair loss may have an important psychological

effect, particularly in younger males.^{1043,1044} There is evidence for a link between early onset androgenetic alopecia and benign prostatic hyper trophy and its accompanying symptoms.¹⁰⁴⁵ In addition, one review and meta-analysis found that vertex pattern androgenetic alopecia is associated with a significantly increased risk of prostate cancer.¹⁰⁴⁶

In females, three distinct patterns of hair loss have been recognized.^{1047–1050} The most common type is a diffuse frontovertex thinning without temporal recession.¹⁰³⁸ The second type is similar to that seen in the male (male pattern alopecia). It is often associated with virilism, although in one study it was found in a significant number of normal postmenopausal women.¹⁰⁵¹ The third pattern is diffuse thinning confined to the vertex and developing after the menopause.¹⁰⁴⁷ A midline part will reveal a characteristic decrease in hair density from the vertex to the front of the scalp.¹⁰⁵² In endocrinologically normal females, the rate of progression of the alopecia is very slow. However, it should always be kept in mind that androgenetic alopecia, in both sexes, may be accompanied or unmasked by other forms of hair loss such as alopecia areata, telogen effluvium, or the hair loss associated with hypothyroidism and even with iron deficiency.^{882,1053} The term 'female pattern hair loss' is preferred by some workers in this field for female patients rather than the term androgenetic alopecia.¹⁰⁵⁴

A new classification of pattern hair loss, applicable to both men and women, has been devised.¹⁰⁵⁵ It has considerable merit, but it is not discussed in detail because it is yet to gain acceptance.¹⁰⁵⁵

Androgenetic alopecia results from a progressive diminution in the size of terminal follicles with each successive cycle and their eventual conversion to vellus follicles.^{1030,1056} This vellus conversion occurs under the influence of androgenetic stimulation or in individuals with genetic predisposition.¹⁰³⁸ The actual mechanism of this miniaturization has never been clearly elucidated. Whiting postulated an abrupt process with a reduction in cell numbers of the dermal papilla.¹⁰⁵⁷ Rebera postulated three mechanisms: an androgen-induced acceleration of the mitotic rate of the matrix that leaves increasingly less time for differentiation; an increased telogen shedding; and the increased number and duration of the lag phase (kenogen), the true resting period of the follicle after telogen.⁷⁶³ Other studies support the notion that the dermal papilla cells represent the androgen target within the hair follicle.¹⁰⁵⁸ The androgen receptor coactivator ARA70/ELE1 is reduced in androgenetic alopecia.¹⁰⁵⁹

The method of inheritance has not been clearly defined. It is probably polygenic. No relationship with the 5 α -reductase gene or the human hairless gene has been found.^{1060–1063} The microsomal enzyme steroid 5 α -reductase is responsible for the conversion of testosterone into the more potent androgen dihydrotestosterone.¹⁰⁶⁴ Androgenetic alopecia is common in adrenoleukodystrophy, an X-linked recessive condition.¹⁰⁶⁵ In contrast, it is uncommon in patients with Kennedy's disease (OMIM 313200), a neurodegenerative disease due to a mutation in the androgen receptor (AR) gene on chromosome Xq11–q12.¹⁰⁶⁶ Racial influences also play a part.¹⁰³⁸ The age-specific prevalence in certain Asian countries is lower than that seen among white people.^{1040,1054,1067}

Elevated urinary¹⁰⁶⁸ and sometimes serum dehydroepiandrosterone levels have been noted in male pattern alopecia.¹⁰⁶⁹ Hair follicles from sites involved with baldness have shown altered levels in the activity of the enzyme responsible for the conversion of certain androgens to their more active metabolites.¹⁰⁷⁰ Hyperandrogenism has been detected in approximately 40% of females with the diffuse type of alopecia.^{1047,1071} Sebum excretion is not increased in females.¹⁰⁷² Polycystic ovaries are frequently the cause of this hyperandrogenetic state.¹⁰⁷¹ Ovarian hyperthecosis may also cause androgenetic alopecia in postmenopausal women.¹⁰⁷³ Antiandrogen therapy (see later) will result in some improvement in up to 50% of patients, but this is usually confined to a decreased rate of hair loss.¹⁰⁷⁴ The IGF-1 axis may be important in the etiology of patterned hair loss in males.^{1075,1076} Increased expression

of IGF-1 messenger RNA levels in the dermal papilla of patients with androgenetic alopecia is associated with response to finasteride,¹⁰⁵⁸ a selective inhibitor of type 2 5 α -reductase, which appears to be capable of reversing the miniaturization of follicles in androgenetic alopecia of younger males but not in postmenopausal women.^{1077,1078} Other mechanisms may also play a role. For example, the low follicular proliferation rate in alopecic areas of scalp, together with anti-apoptotic bcl-2 expression in dermal lymphocytes (resulting in persistent perifollicular inflammatory infiltrates), may promote follicular miniaturization and fibrosis in this condition.¹⁰⁷⁹ There has also been an interest in alterations of hair follicle stem cells or progenitor cells in this disease, especially those cells localized to the bulge region of the follicle. A recent investigation of markers expressed by these cell populations suggests that a defect in conversion of follicular stem cells to progenitor cells may play a role in androgenetic alopecia pathogenesis.¹⁰⁸⁰ In cultures using dermal papilla cells from patients with androgenetic alopecia and hair follicle stem cells, androgens prevent hair differentiation as assessed by keratin-6 expression; the ability of dermal papilla cells to induce differentiation is restored with Wnt signaling activation.¹⁰⁸¹

Treatments include both finasteride 1 mg and minoxidil topical solution (2 or 5%) in males. In female pattern hair loss, finasteride has less efficacy than in males.¹⁰⁸² Spironolactone and cyproterone acetate may be useful in a small subgroup of women.¹⁰⁸³ For all women, unrelated to androgen status, both 2 and 5% topical minoxidil were found to be superior to placebo in the treatment of female pattern hair loss.¹⁰⁸⁴ Hair transplants and cosmetic aids are other important treatments available.¹⁰⁴³

Histopathology^{1085,1086}

The earliest change in androgenetic alopecia is focal basophilic degeneration of the connective tissue sheath of the lower one-third of otherwise normal anagen follicles.¹⁰³⁰ The terminal follicles become progressively smaller, and a proportion regress to the vellus state (Fig. 15.29). This progressive miniaturization of hair follicles and their shafts is best assessed on transverse sections.^{731,1014,1087} The random intermingling of miniaturized and terminal follicles has been called anisotrichosis, analogous to anisocytosis of the peripheral blood film that is characterized by red cells of variable size.¹⁰⁸⁸ Even the matrix and dermal papillae are reduced in size.¹⁰⁸⁹ There is a decreased proliferation of keratinocytes as evidenced by the significant decrease in Ki-67 expression.¹⁰⁹⁰ Only in very advanced stages do the vellus follicles disappear, leaving thin hyaline strands in the dermis.⁷³² Some quiescent terminal follicles are present until a late stage, and it is these that produce hairs under the influence of minoxidil.¹⁰⁹¹ Progressive fibroplasia of the perifollicular sheath appears to be a common process; this may result in the miniaturization of the follicle rather than being a consequence of it.^{1092,1093} Computerized morphometry may be used to quantify follicular size and hair diameter.¹⁰⁹⁴

There is also an increase in the number of telogen and catagen hairs relative to the number of anagen hairs.^{1030,1090} In one study, telogen hairs constituted 16% of the total, compared to 6.5% in normal subjects.¹⁰⁹⁵ This results from a shortening of the anagen cycle. This altered telogen:anagen ratio cannot be appreciated in conventional sections because only a small number of follicles are present in the plane of section. However, if transverse sections are taken of the biopsy, then a greater number of follicles are available for study.⁷³⁴ The decreased hair diameter can also be quantified in these sections.

In the connective tissue streamers that lie beneath the vellus follicles, small elastin bodies can be seen. They are known as Arão-Perkins bodies, and they indicate the sites of the papillae of each preceding generation of follicles.⁷²⁹ They can be stained with the acid orcein method but not the Verhoeff elastic stain.⁷²⁹

Figure 15.29 Androgenetic alopecia. A small vellus follicle is dwarfed by the adjacent sebaceous gland. (H&E)

It is usually suggested that the sebaceous glands are increased in size, number, and lobulation.¹⁰⁸⁶ However, planimetric studies have shown that the total number of sebaceous glands is significantly decreased.¹⁰³⁰ The arrectores eventually diminish in size, but this lags behind the follicles. Accordingly, relatively large arrectores can usually be seen attached to the connective tissue streamers (follicular stela) below the small vellus follicles.

Other changes that may be present include mild vascular dilatation and a mild perivascular round cell infiltrate that often includes mast cells.¹⁰⁸⁶ This has been called 'microinflammation'.¹⁰⁹³ Infrabulbar and peri-isthmic inflammation are rare, but when present, this so-called inflammatory variant, with histological features that overlap alopecia areata and Kossard's chronic stem cell folliculitis, may be an indication of reduced response to treatment.^{1023,1041} Magro *et al.* found a lymphocytic 'microfolliculitis' around the bulge region in a number of patients with androgenetic alopecia, associated with the deposition of IgM and complement components along the epidermal basement membrane zone; this subset of patients appeared to have favorable responses to minocycline, topical corticosteroid, and red light therapy.¹⁰⁹⁶ Multinucleate giant cells are present in up to one-third of biopsies.¹⁰⁹⁷ Small nerve networks, resembling encapsulated

end organs, may be seen. Solar elastosis and some thinning of the dermis may also be present in cases of long standing. Differences in staining for bcl-2 have been observed in clinically affected and unaffected scalp.¹⁰⁹⁸

Female pattern alopecia is usually regarded as having similar, if not identical, morphological features to those seen in males.¹⁰⁸⁵ It has been suggested that the reduction in follicular size might result from a preferential loss of large-diameter terminal hairs rather than a true miniaturization of follicles.¹⁰⁹⁹ One study showed frequent catagen follicles in the female type with a paucity of telogen follicles.¹¹⁰⁰ Numerous vellus follicles were also present.

Dermoscopic findings in female androgenetic alopecia include peripilar brown halos (reflecting perifollicular lymphocytic inflammation), honeycomb scalp pigmentation (probably related to sun exposure), and, in only a few cases, yellow dots (empty follicular ostia).¹¹⁰¹

Differential diagnosis

Distinguishing chronic telogen effluvium from androgenetic alopecia may be difficult, especially when associated in the same patient.¹¹⁰² A distinction can be made based on the number of hairs shed after washing the hair in a standardized way and the length of the hairs shed. Small telogen vellus hairs were associated with androgenetic alopecia, whereas greater shedding (>100 hairs) and length of hair more than 3 cm correlated with telogen effluvium.¹¹⁰² A terminal:vellus ratio of 7:1 is indicative of chronic telogen effluvium, whereas a ratio of 4:1 indicates female androgenetic alopecia.¹¹⁰³ As noted previously, inflammation in alopecia areata is generally more pronounced and peribulbar, whereas it is less frequent, smaller in degree, and more superficially located in androgenetic alopecia. In addition, telogen counts are not as high in androgenetic alopecia as would be expected in alopecia areata or acute telogen effluvium. Senescent alopecia is a slow thinning of scalp hair associated with advancing age. In contrast to androgenetic alopecia, there are normal telogen counts and a normal percentage of terminal follicles with a normal terminal:vellus ratio; however, as is the case with chronic telogen effluvium, overlap of senescent alopecia and androgenetic alopecia certainly occurs.¹¹⁰⁴

TEMPORAL TRIANGULAR ALOPECIA

Temporal triangular alopecia consists of a triangular patch of alopecia with its base extending to the frontotemporal hairline.¹¹⁰⁵⁻¹¹⁰⁸ Most cases develop during the first few years of life; the original designation 'congenital triangular alopecia' is a misnomer.^{1109,1110} It is usually unilateral. Fine vellus hairs are often present in the area.¹¹⁰⁶ It has been misdiagnosed clinically as refractory tinea capitis.¹¹¹¹ Several cases have shown central tufts of short hairs that proved to be terminal hairs on microscopic examination; there is currently no explanation for this finding.¹¹¹²

It has been reported in association with colonic polyposis, eye defects, mental retardation and phakomatosis pigmentovascularis, and also with congenital heart and other anomalies.¹¹¹³⁻¹¹¹⁷ Other associated diseases include Down syndrome and the Dandy-Walker malformation.¹¹¹⁸ It has also occurred in combination with androgenetic alopecia.¹¹¹⁹ The pathogenesis remains unknown.¹¹²⁰

Histopathology

There is replacement of the normal abundant terminal follicles of the scalp by vellus follicles. Nanogen-like hairs are often present. Sebaceous glands and the dermis appear normal.

Trichoscopy (dermoscopy) shows vellus hairs surrounded by normal terminal hairs, without hair breakage, tapering hairs, or black or yellow dots.¹¹²¹

ANAGEN DEFLUVIUM

Anagen defluvium (anagen effluvium) is the loss of anagen hairs, either because they are defective and break or, rarely, because they are easily detached from the hair follicles.⁷³² The hair loss may be patterned or diffuse, and it appears 1 month or less after the causative event, much faster than the hair loss in telogen effluvium.⁸⁶⁶

Defective hairs that break easily occur in several hair shaft abnormalities, such as pili torti, trichorrhexis nodosa, and monilethrix.⁷³² They also develop following antimitotic agents, various drugs, thallium, arsenic, vitamin A intoxication, and X-ray therapy.⁷³² Although anagen defluvium (effluvium) has been regarded as the method of hair loss, a recent study implicated telogen effluvium as the cause.⁸⁸⁴ Other causes include trauma, thyroid disease, hypopituitarism, deficiency states, infections of the follicle or hair shaft, and alopecia areata.^{737,866}

Easy detachment of anagen hairs is a rare cause of anagen defluvium, occurring in follicular mucinosis, lymphomatous infiltration of the hair follicles, and the rare loose anagen syndrome (see later).

In most instances, the diagnosis is made on clinical grounds, and scalp biopsies are rarely performed. Two disorders, the loose anagen syndrome and drug alopecia, are considered in further detail. Note that various mechanisms may be involved in drug alopecias.

LOOSE ANAGEN SYNDROME

Loose anagen (hair) syndrome (OMIM 600628) is a recently delineated entity of childhood in which anagen hairs are easily pulled from the scalp of affected individuals, who present with diffuse hair loss.^{1122–1126} It results from a disorder of adhesion of anagen hairs between the hair cuticle and inner root sheath cuticle leading to impaired anchorage of hairs to their follicle.^{1127,1128} It may sometimes be mimicked by alopecia areata.¹¹²⁹ Some improvement in the alopecia occurs with increasing age. Children usually present with slow-growing hair that seldom requires cutting.¹¹³⁰ Short anagen syndrome also presents in this way.⁸⁴² Adult onset has been recorded.

The hair-pluck trichogram shows a high proportion of loose anagen hairs, but the hair-pull test varies over time.¹¹²⁷ There are even periods when no hairs can be obtained.¹¹²⁷

Trichotillomania, probably related to child abuse, has been superimposed on this syndrome, increasing the hair loss.¹¹³¹

The syndrome has been associated with ectodermal dysplasia, with woolly hair,¹¹³² and with a Noonan-like syndrome (OMIM 607721).¹¹³³ A mutation in the hair keratin gene *K6HF* (now *KRT86*) has been found in a few cases.¹¹³⁰

Histopathology

Abnormal keratinization of Huxley's and Henle's layers of the inner root sheath has been found in some samples.¹¹²³ In one study of this syndrome, there were thickened, tortuous keratinized Henle cell strands, vacuolar changes in Huxley cells, and irregular keratinization of hair cuticle cells.¹¹³⁴ The keratogenous zone of the follicle appears shorter than normal.¹¹³⁵ Marked cleft formation between hair shafts and regressively altered inner root sheaths were noted in another study.¹¹²² The easily extracted hairs are misshapen anagen hairs without external root sheaths.¹¹²³

Electron microscopy

Ultrastructural findings include intercellular edema in the prekeratinized Huxley cell layer and abnormal keratinization of Henle and inner root sheath cuticle cells, manifesting as uneven filamentous arrangements.¹¹³⁴

DRUG-INDUCED ALOPECIA

Alopecia induced by drugs usually presents as diffuse, nonscarring hair loss that is reversible upon withdrawal of the drug.^{1135–1138} It is a common complication of the various antimitotic agents used in the chemotherapy of cancer,¹¹³⁹ but it may also occur as a rare complication of other therapeutic drugs.¹¹⁴⁰ It is now being described with the EGF-R inhibitors.^{1141,1142} They may affect both growth and hair texture. A nationwide outbreak of alopecia has been reported in the United States, associated with the use of a commercial hair-straightening product.¹¹⁴³ The low pH of the product may have been responsible. Hair care products are widely used, and although sometimes implicated as a cause of hair loss, this complication is exceedingly rare, if it happens at all.¹¹⁴⁴

Drugs may interfere with hair growth in a number of different ways. For example, thallium,¹¹⁴⁵ excess vitamin A, retinoids, and certain cholesterol-lowering drugs interfere with the keratinization of the hair follicle.^{1136,1146,1147} The antimitotic drugs interfere with hair growth in the anagen phase by interrupting the normal replication of the hair matrix cells.¹¹³⁷ Other drugs induce telogen effluvium, and the follicles remain in the resting phase.

In addition to those already listed, drugs that may induce alopecia include anticoagulants; antithyroid drugs; chemicals used in straightening hair;^{1143,1148} anticonvulsants; hormone-related substances such as clomiphene; heavy metals such as lead, bismuth, arsenic, gold, mercury, and lithium; antibacterial agents such as gentamicin, nitrofurantoin, and ethambutol; and nonsteroidal anti-inflammatory or antihyperuricemic agents such as naproxen, ibuprofen, allopurinol, probenecid, and indomethacin.^{1136,1137,1149} The anticonvulsant valproate may cause depigmentation of hair rather than alopecia.¹¹⁵⁰ Drugs that have been incriminated rarely include amphetamines, vasopressin,¹¹⁵¹ β -blocking agents, cimetidine, levodopa, methysergide, penicillamine, bromocriptine, borates,¹¹⁵² quinacrine (mepacrine), selenium, and tricyclic antidepressants.¹¹³⁷ Localized alopecia has been reported at the injection site of IFN- α -2b.¹¹⁵³ Erlotinib, a tyrosine kinase inhibitor that acts on EGF-R, has produced alopecia associated with numerous pustules on the scalp. In fact, alopecia has been reported in 5% of patients on EGF-R inhibitors.¹¹⁵⁴ A detailed listing is contained in the review article by Pillans and Woods.¹¹³⁸

Histopathology

Drugs that produce telogen effluvium will induce catagen changes in many of the follicles. By the time a biopsy is taken, the follicles have usually entered the telogen phase. The antimitotic agents also induce premature catagen transformation. At a later stage, the follicles enter anagen, but their growth is then arrested at various stages of development. Alopecia associated with EGF-R inhibitors shows inflammatory infiltrates containing lymphocytes, plasma cells, neutrophils, and some eosinophils, sometimes with increased catagen/telogen follicles and scarring.¹¹⁵⁵

SCARRING ALOPECIAS

The scarring (cicatricial) alopecias are an etiologically diverse group that share in common the destruction of hair follicles associated with atrophy and/or scarring of the affected area, usually leading to permanent hair loss.¹¹⁵⁶ They may result from intrinsic inflammation of the hair follicle (folliculitis) or destruction of follicles by an inflammatory or neoplastic process external to them.¹¹⁵⁷

Recently, attention has focused on the role of the sebaceous gland in scarring alopecia. Stenn and colleagues have drawn attention to the fact that the sebaceous gland is lost in the early phases of scarring alopecia.¹¹⁵⁸

The mutant asebia mouse has hypoplastic sebaceous glands. It soon develops a scarring alopecia, supporting the theory that primary sebaceous gland pathology may be involved in some scarring alopecias.¹¹⁵⁸

The scarring alopecias may be classified on an etiological basis as follows:¹¹⁵⁷

Developmental and related disorders

- Epidermal nevus
- Aplasia cutis
- Incontinentia pigmenti
- Keratosis pilaris atrophicans
- Porokeratosis of Mibelli
- Ichthyosis vulgaris
- Darier’s disease
- Epidermolysis bullosa (recessive dystrophic)
- Polyostotic fibrous dysplasia

Physical injuries

- Mechanical trauma, including pressure/traction
- Thermal, electric, and petrol burns
- Radiodermatitis
- Therapeutic embolization¹¹⁵⁹

Specific infections

- Certain fungal infections (including kerion and favus)
- Herpes zoster and varicella
- Pyogenic folliculitides
- Lupus vulgaris
- Syphilis (late stages)
- Leishmaniasis

Specific dermatoses

- Lichen planus and variants
- Lupus erythematosus
- Scleroderma and morphea
- Necrobiosis lipoidica
- Necrobiotic xanthogranuloma
- Lichen sclerosus et atrophicus
- Sarcoidosis¹¹⁶⁰
- Amyloidosis
- Cicatricial pemphigoid
- Follicular mucinosis
- Folliculitis decalvans
- Dissecting cellulitis of the scalp

Neoplasms (alopecia neoplastica)

- Basal and squamous cell carcinomas
- Angiosarcoma
- Lymphoma
- Secondary tumors

Idiopathic

- Idiopathic scarring alopecia (pseudopelade)
- Traction alopecia with scarring
- Postmenopausal frontal fibrosing alopecia
- Fibrosing alopecia in a pattern distribution
- Tufted-hair folliculitis.

With the exception of the idiopathic scarring alopecias, the previous conditions are all discussed in other sections of this volume.

Attention has been given in recent years to the regrouping of some of the scarring alopecias into an orderly classification. Sperling, Solomon, and Whiting examined the central centrifugal scarring alopecias,¹¹⁶¹ while Sullivan and Kossard grouped together the pustular scarring alopecias.¹¹⁶² These concepts are considered next. Readers are

Table 15.2 Causes of pustular scarring alopecias

These changes are frequently observed in this form of alopecia. (H&E)

referred to the etiological classification presented previously. It still provides a convenient checklist of the various scarring alopecias.

Different approaches to scarring alopecias

Two publications have attempted to bring some order to the confusing area of scarring alopecias. Although not followed here, they are worthy of some mention. Sullivan and Kossard provided a detailed classification of the scarring alopecias.¹¹⁶² Their categorization of the *pustular scarring alopecias* is worth repeating (Table 15.2).

The second publication, by Sperling, Solomon, and Whiting, discussed the concept of *central centrifugal scarring alopecia* (Fig. 15.30).¹¹⁶¹ This term is a clinical one that includes patients with (1) hair loss centered on the crown or vertex, (2) chronic and progressive disease with eventual ‘burnout’, (3) symmetrical expansion, and (4) clinical and histological evidence of peripheral inflammation.^{1161,1163} Their concept encompasses the following:

- Follicular degeneration syndrome
- Pseudopelade (idiopathic scarring alopecia)
- Folliculitis decalvans
- Tufted folliculitis.

However, whereas fibrosing alopecia in a pattern distribution would seem to fit this definition, frontal fibrosing alopecia does not. Yet they would logically seem to fit together in any clinicopathological correlation. Furthermore, the previous classification seems to include disorders with diverse etiologies, at least in our current state of

'knowledge'.^{1164,1165} Another criticism of this concept has been provided by Ackerman and colleagues, who point out that there is no such entity as the follicular degeneration syndrome, which is in reality a traction alopecia.⁸⁶³ Interestingly, traction alopecia, fibrosing alopecia in a pattern distribution, and postmenopausal frontal fibrosing alopecia all share a lichenoid perifolliculitis in the early stages. It may be that various stimuli are capable of altering the antigenicity of follicular cells, leading to a lichenoid (cell-mediated) reaction.

Classification of cicatricial alopecias by inflammatory infiltrate

A histopathological classification of cicatricial alopecias is given here. It is based on the workshop sponsored by the North American Hair Research Society held in 2001¹¹⁶⁶ and on other subsequent publications.^{731,1167–1169} Scarring alopecia associated with mastocytosis is not accommodated in this classification.¹¹⁷⁰

Lymphocytic cicatricial alopecias

- Cutaneous lupus erythematosus
- Lichen planopilaris/frontal fibrosing alopecia/Graham Little–Piccardi–Lassueur syndrome
- Central centrifugal alopecia (including 'hot comb' alopecia, traction alopecia with scarring) – concept not accepted by all¹¹⁶⁹
- Alopecia mucinosa
- Keratosis follicularis spinulosa decalvans
- Classic pseudopelade of Brocq (including idiopathic scarring alopecia)

Neutrophilic cicatricial alopecias

- Folliculitis decalvans
- Tufted folliculitis
- Dissecting folliculitis

Mixed lymphocytic/neutrophilic cicatricial alopecias

- Folliculitis (acne) keloidalis
- Acne necrotica
- Erosive pustular dermatosis

Nonspecific (end-stage) cicatricial alopecia

- Many different inflammatory alopecias can have nonspecific end-stage features.

In a publication by several experienced dermatopathologists, a clinicopathological correlation of six clinically distinct primary cicatricial alopecias was attempted using this method: lichen planopilaris, frontal fibrosing alopecia, pseudopelade (Brocq), centrifugal alopecia, folliculitis decalvans, and tufted folliculitis. The lymphocytic and neutrophilic groups (folliculitis decalvans and tufted folliculitis) could be readily distinguished according to the earlier North American Hair Research Society classification,¹¹⁶⁶ but within the two groups, the clinically distinct entities could not be distinguished on their histopathology.¹¹⁶⁷ Premature desquamation of the inner root sheath has been regarded as a defining histological feature of central cicatricial alopecia, but it can also be seen in many other types of alopecia.^{360,1171}

In a study of 112 patients from Vancouver, Canada, the ratio of lymphocytic to neutrophilic cicatricial alopecias was 4:1.¹¹⁷² Whereas lymphocytic alopecias had a tendency to affect middle-aged women, the neutrophilic ones had a predilection for middle-aged men. The pathogenesis of the scarring alopecias has received recent attention. It has been suggested that destruction of follicular stem cells is a possible mechanism in lichen planopilaris, the prototype scarring alopecia (see p. 46). A subsequent study has failed to confirm a T-cell-mediated destruction of follicular bulge stem cells in primary scarring alopecia.¹¹⁷³

Treatment options for the lymphocytic variant include corticosteroids, antimalarials, and isotretinoin. Antibiotics, corticosteroids, and

isotretinoin can be used for the neutrophilic ones.^{1169,1172} In 2008, Harries *et al.* published an excellent, evidence-based review on the treatment options for the various primary cicatricial alopecias.¹¹⁷⁴

IDIOPATHIC SCARRING ALOPECIA (PSEUDOPELADE)

Idiopathic scarring alopecia (fibrosing alopecia,^{729,1022} alopecia cicatricata, pseudopelade) is a rare, asymptomatic form of scarring alopecia in which there is patchy hair loss not accompanied by any clinical evidence of folliculitis, lichen planus, lupus erythematosus, or any of the specific diseases listed previously.¹¹⁷⁵ The term 'idiopathic scarring alopecia' is preferred to the more commonly employed name *pseudopelade*, which has been used in the past in a variety of contexts:^{1176–1178} it has been applied to end-stage scarring alopecias following known dermatoses such as lichen planus and lupus erythematosus.^{1179,1180} It is conceded that the term 'pseudopelade' has some use in a clinical setting to refer to a scarring alopecia, the cause of which is not yet known, but it should not be used to refer to a clinicopathological entity.¹¹⁸¹ The term 'idiopathic scarring alopecia' is used infrequently these days.

Idiopathic scarring alopecia tends to affect females older than the age of 40 years. It has an insidious onset and a chronic, usually slowly progressive course. It results in slightly depressed patches of irreversible hair loss that may occur singly or in groups that have been described as resembling 'footprints in the snow'.⁷³² The small patches may coalesce to form larger patches of scarring alopecia. Both the scalp and the beard area were involved in one patient.¹¹⁸² As the designation 'idiopathic' implies, the etiology is unknown. Pseudopelade has been reported in two brothers.¹¹⁸³

Fibrogenic cytokines (IL-4, IL-6, basic fibroblast growth factor, and TGF- β) were demonstrated in all scarring alopecias tested in one series.¹¹⁸⁴

Histopathology^{729,1022}

In established lesions, there is loss of hair follicles and sebaceous glands, and these are replaced by bands of fibrous tissue containing elastic fibers (Fig. 15.31). These bands extend above the level of the attachment of the arrectores pilorum, in contrast to normal telogen in which the fibrous tissue replaces only the deeper part of the hair follicle. In transverse sections, a prominent perifollicular lamellar fibroplasia is usually seen.^{735,1185}

In early lesions, a moderately heavy infiltrate of lymphocytes surrounds the upper two-thirds of the follicle. It has been suggested that these may extend into the follicle, producing its massive apoptotic involution.¹¹⁸⁶ The epidermis is not involved by the inflammatory infiltrate. In late lesions, the epidermis may show some atrophic changes with loss of the rete ridge pattern.

The orcein and Verhoeff–van Gieson elastic stains may provide useful information in the scarring alopecias.^{1022,1187} Whereas the fibrous tracts associated with the scarring alopecia of lichen planopilaris and lupus erythematosus are usually devoid of elastic fibers (this loss is more extensive in lupus erythematosus than in lichen planopilaris), there are elastic fibers in the fibrous tracts of idiopathic scarring alopecia and traction alopecia with scarring.¹¹⁸⁷ In a proportion of cases, elastic fibers develop around the lower cyclic portion of the hair follicle.¹⁰²²

Direct immunofluorescence may also assist in the diagnosis of the scarring alopecias.¹¹⁸⁸ In idiopathic scarring alopecia, immunofluorescence is negative, in contrast to lupus erythematosus, in which a band of immunoglobulins and complement may be found along the basement membrane zone and surrounding hair follicles.¹¹⁸⁸ In lichen planus, colloid bodies containing IgM and often C3 are present beneath

Figure 15.31 Idiopathic scarring alopecia. A band of fibrous tissue is present at the site of a destroyed hair follicle. (H&E)

the epidermis and around hair follicles.¹¹⁸⁸ In ‘burnt-out’ lesions, direct immunofluorescence may be negative.

TRACTION ALOPECIA WITH SCARRING

The term ‘traction alopecia with scarring’ is used in preference to ‘hot comb’ alopecia, central progressive alopecia in black females, and the follicular degeneration syndrome for a form of scarring alopecia involving predominantly the crown of the scalp.^{1189,1190} Hairs at the periphery of the scalp are spared. It primarily affects black women.¹¹⁹¹ Traction alopecia was present in 22.6% of African adults ($n = 874$) examined in Cape Town, South Africa; its prevalence was higher in women than in men.¹¹⁹² It also occurs in African schoolchildren.¹¹⁹³ Relaxers – chemicals used to straighten African hair – can produce a similar clinicopathological picture.¹¹⁹⁴ Traction alopecia can be reduced/prevented by avoiding hairstyles with traction, especially to chemically processed hair.¹¹⁹⁵

Whereas minor degrees of traction can produce hair loss without significant scarring, as in trichotillomania (see p. 484), prolonged and recurrent severe traction can result in scarring. Ackerman and colleagues presented a detailed study of this entity, noting that there is

no follicular degeneration in these cases, and that the use of this term is no longer justified.⁸⁶³

Pressure (postoperative) alopecia is a related disorder seen rarely in patients who have undergone a major surgical procedure.^{741,1196} A few weeks later, there is nearly total hair loss from the pressurized area with sharp demarcation. The occipital area is commonly involved. Scarring also results in some of these cases.

Histopathology

As defined by Ackerman and colleagues, biopsies at an early stage show a lichenoid perifolliculitis in which infundibula are enveloped by lymphocytes with progressive perifollicular fibroplasia.⁸⁶³ In fully developed lesions, the infiltrate is sparse and the lower part of the infundibulum and isthmus are thinned, consequent to the fibroplasia. A granulomatous reaction to extravasated cornified material is present. This is followed by a loss of follicles and increased fibrosis with extension into the subcutis.

In the early stages of *pressure alopecia*, there is often vascular thrombosis and inflammation. Nearly all the follicles are in catagen/telogen. Trichomalacia and pigment casts may also be found.⁷⁴¹ Infundibular dilatation of hair follicles may also be a feature in cases resulting from pressure.¹¹⁹⁶

The Verhoeff–van Gieson elastic stain shows a hyalinized dermis with markedly thickened elastic fibers. The elastin sheath is preserved at the periphery of the broad fibrous tracts.¹¹⁸⁷

POSTMENOPAUSAL FRONTAL FIBROSING ALOPECIA

The term ‘postmenopausal frontal fibrosing alopecia’ has been used for a progressive frontal scarring alopecia associated with perifollicular erythema.^{1197,1198} Scarring alopecia of the sideburn areas has been reported in men with this condition.¹¹⁹⁹ The eyebrows and axillary hair are lost in some cases,¹²⁰⁰ leading to the suggestion that it is related to the Graham Little–Piccardi–Lassueur syndrome.¹²⁰¹ There are examples with generalized hair loss,¹²⁰² loss of body hair,¹²⁰³ and acute hair loss on the limbs.¹²⁰⁴ Kossard and colleagues reported 16 cases, suggesting that it is more common than the paucity of reports would indicate.¹²⁰⁵ The absence of lesions of lichen planus elsewhere in most cases led to the suggestion that these cases might represent a unique follicular destruction syndrome mediated by lymphocytes and triggered by postmenopausal events.¹¹⁹⁷ However, it has now been reported in a premenopausal woman with cutaneous lichen planus¹²⁰⁶ and has been accompanied by lichen planus pigmentosus.¹²⁰⁷ It is best regarded as a variant of lichen planopilaris with selective involvement of certain androgen-dependent areas (see p. 46).^{1205,1208} It has followed hair transplantation for androgenetic alopecia.¹²⁰⁹ One study showed immunohistochemical expression of Snail-1, a marker of epithelial–mesenchymal transitions, in the fibrotic dermis of a patient with frontal fibrosing alopecia. This suggests that the fibrosis in this disease could be caused by fibroblasts derived, in part, from hair follicle cells through an epithelial–mesenchymal transition process.¹²¹⁰ In general, treatment has been disappointing in this disease. In some patients who have been treated with finasteride, the condition has not progressed, which suggests that androgens may be partly responsible.¹²⁰⁸ Intralesional and topical corticosteroids may also stop the progression of the disease.¹²⁰⁰ Hydroxychloroquine has been reported to reduce signs and symptoms, but it is most beneficial within the first 6 months of use.¹²¹¹

Histopathology

The histological features are generally thought to be indistinguishable from those seen in lichen planopilaris, but Tosti and colleagues stated that unlike lichen planopilaris, the lymphocytic infiltrate and fibrosis

Figure 15.32 Frontal fibrosing alopecia. There are vacuolar changes, apoptosis, and clefting between follicular epithelium and the surrounding stromal fibrosis. (H&E)

affect selectively the intermediate and the vellus-like follicles.¹²⁰⁸ This is supported by the finding of what appear to be non-inflammatory follicular papules, especially in the temporal area, in some patients with frontal fibrosing alopecia. These papules show perifollicular lymphocytic inflammation around the infundibulum and isthmus regions of vellus follicles.¹²¹² On the other hand, a suggested diagnostic feature of *early* frontal fibrosing alopecia is the ‘follicular triad’, best found when guided by dermoscopic findings of peripilar casts. The follicular triad consists of lichenoid infiltrates and perifollicular fibrosis around anagen, telogen, and vellus follicles (**Fig. 15.32**).¹²¹³ It may be that the more prevalent involvement of intermediate and vellus follicles usually reported in frontal fibrosing alopecia is related to the normal anatomy of the frontal hairline, which may contain more vellus and intermediate follicles.¹²¹³ Other authors have reported more apoptosis in frontal alopecia than in lichen planopilaris and less follicular inflammation.¹²¹⁴

Dermoscopy can be used to distinguish the condition from alopecia areata.¹²¹⁵ The findings include loss of follicular orifices, perifollicular scale, and mild perifollicular erythema;¹²¹⁶ there are no yellow dots, as characteristic of alopecia areata.¹²¹⁵ Videodermoscopy in patients with pathologically confirmed frontal fibrosing alopecia also shows an absence of vellus hairs. This may be explainable by the early scarring that affects both terminal and vellus hairs; with disease progression, the recessed hairline may no longer contain vellus hairs.¹²¹⁷

FIBROSING ALOPECIA IN A PATTERN DISTRIBUTION

Fibrosing alopecia in a pattern distribution appears to be another variant of lichen planopilaris in which the immune reaction is directed against miniaturized follicles of androgenetic alopecia.¹²¹⁸ That is, these persons develop inflammatory scarring alopecia affecting only the balding central scalp.¹¹⁶¹ The lichenoid infiltrate targets the upper follicle. Late lesions resemble end-stage lichen planopilaris.¹²¹⁸

FOLLICULITIS DECALVANS

Folliculitis decalvans is sometimes considered to be a primary scarring alopecia. However, because inflammation of the follicle is a major

feature, it has been considered with the folliculitides on page 467. Hair straightening and other cosmetic practices are a common cause of this condition in African-American women.¹²¹⁹ Sperling believes that folliculitis decalvans in most cases represents a highly inflammatory form of central centrifugal cicatricial alopecia.³⁶⁰

TUFTED-HAIR FOLLICULITIS

Tufted-hair folliculitis is characterized by areas of scarring alopecia with tufts of 10–20 hairs emerging from single follicular openings.^{1220–1222} There is a predilection for the parietal and occipital areas.¹²²³ It is most likely a consequence of bacterial folliculitis involving the upper and mid follicle with rupture and scarring. It may complicate folliculitis decalvans,^{361,362} folliculitis keloidalis nuchae (acne keloidalis), and pemphigus vulgaris.^{1224–1226} It has followed the use of cyclosporine,¹²²⁷ the HER2 inhibitor trastuzumab,¹²²⁸ and chronic systemic corticosteroids.¹²²⁹

Antibiotics, both topical and systemic, are commonly used treatments, but complete cure is rare.¹²²³ A combined therapy of oral rifampicin and oral clindamycin for 10 weeks has been used.³⁶² It was effective in approximately half of the cases.³⁶²

Histopathology

A biopsy is usually carried out at a late stage when there is folliculitis, perifolliculitis, and scarring.¹²³⁰ The characteristic feature is the presence of several closely set, complete follicles with a common follicular opening from which multiple hair shafts emerge.¹²²²

MISCELLANEOUS ALOPECIAS

There is one rare form of alopecia that does not fit neatly into any of the other categories. It is called lipedematous alopecia.

LIPEDEMATOUS ALOPECIA

Lipedematous alopecia, an acquired condition of unknown etiology, is characterized by a thick, boggy scalp with varying degrees of hair loss, occurring predominantly in adult black females.^{1231,1232} It is associated with a nonscarring but permanent alopecia.¹²³³ Irritation and pruritus are often present.¹²³⁴ It has been reported in association with discoid lupus erythematosus.¹²³⁵ There is doubling of the scalp thickness due to expansion of the subcutaneous fat layer.¹²³⁶ The term ‘**lipedematous scalp**’ has been used for cases without hair loss.¹²³⁷ The diagnosis can be confirmed by ultrasound. Lipedema of the extremities may be a related condition (see Chapter 17).¹²³⁸

Surgical debulking has been described as a method of management.¹²³⁹

Histopathology

There may be mild hyperkeratosis, acanthosis, and keratinous follicular plugging. Hair follicles are usually reduced in number. The most noticeable feature is a thickening of the subcutis, which appears to encroach upon the dermis (**Fig. 15.33**).¹²³⁶ The subcutis is edematous with disruption of fat architecture and cellular integrity. No inflammation or lipomembranous change has been described. Increased mucin was described in one case¹²³⁷ but specifically excluded in others.^{1231,1240} The author has seen cases in which fat overgrowth without significant lymphedema produced a clinically similar condition. Lymphangiectasia has been present in two cases with hair loss.¹²⁴⁰ The significance of this change is uncertain.

The colocalization of lipedematous scalp and nevus lipomatosus superficialis has been reported.¹²⁴¹

Figure 15.33 Lipedematous alopecia. The subcutaneous fat encroaches on the dermis and extends to the level of the sebaceous gland. (H&E)

MISCELLANEOUS DISORDERS

In this section, the following miscellaneous topics are covered:

- Pilosebaceous disorders
- Apocrine disorders
- Eccrine disorders
- Vestibular gland disorders.

A brief account of the embryology and anatomy of the sebaceous, apocrine, and eccrine glands is also given.

PILOSEBACEOUS DISORDERS

The normal hair follicle was discussed previously in this chapter. Its embryology and structure are considered on page 458 and the normal hair cycle on page 481.

The structure of the sebaceous gland will be considered here, followed by a discussion of various ‘miscellaneous’ disorders of the pilosebaceous unit, not previously considered.

The normal sebaceous gland

The sebaceous gland develops as a bud from the primordial hair follicle in the 13th to 15th week of fetal life. It is a multilobular gland connected by a short duct to the hair follicle at the junction of the infundibulum and isthmus. The gland is composed of a peripheral zone of basal cells that accumulate lipid in the cytoplasm as they move toward the center of the gland. The sebocytes eventually disintegrate at the level of the duct, releasing the mature sebaceous product, known as sebum, which acts as an emollient, bacteriostat, insulator, and pheromone. Sebaceous gland secretion is aided by contraction of the arrector pili muscle.¹²⁴² Both structures form a follicular unit with the attached follicle.¹²⁴³

Sebaceous glands are distributed throughout the body except for the palms and soles. They are largest and most numerous in the skin of the face and the upper part of the trunk (the so-called ‘seborrheic areas’). The meibomian glands in the tarsus and the glands of Zeis at the lid margin are modified sebaceous glands.

The sebaceous glands increase in size at puberty. They atrophy in old age, particularly in females, although the number of glands remains the same. No major changes appear until the eighth decade of life in males.¹²⁴⁴ Overexpression of the aging-associated gene *Smad7* correlates with sebaceous gland hyperplasia.¹²⁴⁴

Miscellaneous disorders of the pilosebaceous unit

Several diseases of the pilosebaceous unit do not fit readily into any of the categories discussed previously. They include hypertrichosis, keratosis pilaris, keratosis pilaris atrophicans, follicular spicules, lichen spinulosus, rosacea, pyoderma faciale, and neutrophilic sebaceous adenitis. Rosacea is traditionally included with the pilosebaceous disorders, although there is increasing evidence that it is not a primary disease of the appendages.

HYPERTRICHOSIS

Hypertrichosis refers to the growth of hair on any part of the body in excess of the amount usually present in persons of the same age, race, and sex.¹²⁴⁵ Androgen-induced hair growth (hirsutism) is not included in this definition.¹²⁴⁶ Several distinct clinical forms exist.¹²⁴⁷

Congenital hypertrichosis lanuginosa

Congenital hypertrichosis lanuginosa is an exceedingly rare familial disorder, often inherited as an autosomal dominant trait, in which there is excessive growth of lanugo hair.¹²⁴⁸ Dental and eye abnormalities may also be present.¹²⁴⁹ Sporadic cases also occur.¹²⁵⁰

Terminal and lanugo hairs are present in the hypertrichosis associated with gingival fibromatosis (OMIM 135400), a rare autosomal dominant syndrome.^{1251,1252}

Acquired hypertrichosis lanuginosa

Acquired hypertrichosis lanuginosa is usually generalized, except for the palms and soles. An important cause is an underlying cancer, usually of epithelial type,¹²⁵³ although rarely a lymphoma is present.¹²⁵⁴ Hair growth may antedate the appearance of the tumor by months to several years.^{1255,1256} There may be rapid resolution after treatment of the malignancy.¹²⁵⁷ The pathogenesis is unknown. Vellus hairs, intermediate forms, and terminal hairs may also be increased in paraneoplastic cases,¹²⁵⁰ as well as in cases of porphyria, malnutrition and brain injury, and, usually reversibly, in patients taking streptomycin, phenytoin (diphenylhydantoin), corticosteroids, penicillamine, psoralens, benoxaprofen, the vasodilators diazoxide and minoxidil,¹²⁵⁸ and cyclosporin A (cyclosporine).^{1245,1259,1260} Minoxidil-induced hypertrichosis may be limited to the face.¹²⁶¹

Congenital circumscribed hypertrichosis¹²⁴⁵

Localized areas of hypertrichosis can be seen in congenital pigmented nevi, Becker’s nevus, overlying a neurofibroma, scrotal hair,¹²⁶² hairy pinnae, hairy elbows (OMIM 139600),^{1252,1263} anterior and posterior cervical hypertrichosis (OMIM 239840),^{1252,1264,1265} nevroid hypertrichosis,^{1266,1267} spinal dysraphism (‘faun-tail’),^{1268,1269} ectopic cilia,¹²⁷⁰ and in depigmented hypertrichosis following Blaschko’s lines.¹²⁷¹ Nevroid hypertrichosis is a congenital circumscribed patch of terminal hair without other abnormalities. It is usually solitary.¹²⁴² It may be linear.¹²⁷²

Nevoid hypertrichosis has been successfully treated with the alexandrite laser.¹²⁷³

Moderate hypertrichosis of the lower extremities has been reported in a patient with mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes (MELAS syndrome).¹²⁷⁴ Other congenital syndromes associated with hypertrichosis¹²⁷⁵ are listed in the review of this subject by Wendelin *et al.* in 2003.¹²⁴⁷ A new entity reported since this review is the H syndrome (OMIM 612391), a genodermatosis characterized by indurated, hyperpigmented, and hypertrichotic skin with numerous systemic manifestations, including short stature, cardiac anomalies, hypogonadism, and hepatosplenomegaly.¹²⁷⁶

Acquired circumscribed hypertrichosis¹²⁴⁵

Hypertrichosis may develop at sites of persistent friction and irritation in association with plaster casts and at sites of inflammation, including insect bites.¹²⁷⁷ Trauma may explain the paradoxical hypertrichosis that followed laser epilation.¹²⁷⁸ It has also developed at the site of measles immunization¹²⁷⁹ and in association with a verruca vulgaris.¹²⁸⁰ It developed on the glans penis in an adult male, but no etiology was apparent.¹²⁸¹ Facial hypertrichosis has been induced by efalizumab¹²⁸² and by cetuximab.¹²⁸³ Hypertrichosis of the eyelashes can be caused by drugs that lower intraocular pressure, such as latanoprost and bimatoprost.¹²⁸⁴

There is extensive clinical evidence for the effectiveness of laser and light-based treatments in the removal of unwanted hair.¹²⁸⁵ Their mechanism of action is unknown. A study of follicular stem cells following laser treatment showed thermally altered hair shafts but intact stem cells, suggesting that functional alteration, rather than their destruction, may underlie the clinical efficacy of this treatment. Alternatively, completely different mechanisms may be involved.¹²⁸⁵

Histopathology

Little has been written on the histopathology of hypertrichosis.¹²⁵⁹ In the acquired form, the follicles have been reported to be small and deviated from their normal vertical position. They extend obliquely or even parallel to the epidermis and contain thin unmedullated hairs. The follicles are surrounded by small lipidized mantles representing sebaceous ducts showing early glandular differentiation.¹²⁸⁶

KERATOSIS PILARIS

Keratosis pilaris (OMIM 604093) is a disorder of keratinization involving the infundibulum of the hair follicle. It is a common condition, being found in up to 5% of adult males and in 30% of females, particularly those showing hyperandrogenism and obesity.¹²⁸⁷ These figures obviously include cases of keratosis pilaris rubra (see later), which has not always been distinguished from keratosis pilaris. It is also increased in patients with insulin-dependent diabetes mellitus.¹²⁸⁸ The lesions, which vary from subtle follicular excrescences to more prominent follicular spikes, are found most often on the posterior aspect of the upper part of the arms and on the lateral aspect of the thighs and buttocks.¹²⁸⁹ Unilateral involvement has been reported.¹²⁹⁰ Onset is usually in childhood, with remission in adulthood in some patients.¹²⁹¹ A precocious variant of keratosis pilaris begins in early childhood and presents as profuse involvement of the extremities and cheeks.¹²⁹² Follicular keratotic plugs resembling keratosis pilaris may be found in keratosis pilaris rubra, keratosis pilaris atrophicans (see later), lichen spinulosus (see p. 500), pityriasis rubra pilaris, ichthyosis, psoriasis, some eczemas, lithium therapy,¹²⁹³ and uremia.^{1287,1294,1295} Keratosis pilaris has also been reported in the ectodermal dysplasias^{1290,1296,1297} and in association with woolly hair. Large follicular keratotic plugs are seen in the amputation stumps of some patients with lower limb

amputations and ill-fitting prostheses;^{1298,1299} they have also been seen as an idiopathic phenomenon.¹³⁰⁰ Follicular keratosis of the chin also appears to be due to prolonged pressure and friction.¹³⁰¹

Keratosis pilaris rubra is characterized by substantial erythema, widespread involvement, and persistence after puberty.¹³⁰¹ There is no atrophy or hyperpigmentation as seen in the atrophic variants.¹³⁰¹ Erythema is sometimes present in keratosis pilaris, but it is usually mild and limited to the perifollicular skin.

It is thought that androgenic stimulation of the pilosebaceous follicle may result in the hyperkeratinization of the infundibulum.¹²⁸⁷ Flushing by autonomic dysregulation may have a role in the rubra variant.¹²⁹¹ A keratosis pilaris-like eruption has been associated with the BRAF kinase inhibitor vemurafenib¹³⁰² and an investigative BRAF kinase inhibitor, PLX 4032.¹³⁰³

Numerous treatments have been used, reflecting the lack of a consistent response to any therapy. They include emollients, various keratolytics, or a combination; topical corticosteroids; pulsed-dye laser; and retinoids, both topical or systemic.¹²⁹¹

Histopathology

A keratin plug fills the infundibulum of the hair follicle and protrudes above the surface for a variable distance (Fig. 15.34). Serial sections are sometimes necessary to show the plug to best advantage. A very sparse lymphocytic infiltrate may be present in the dermis adjacent to the follicular infundibulum. Coiled hair shafts may be found within the follicular infundibula; this finding has led to the suggestion that these coiled hairs may rupture follicular epithelia, with resulting inflammation and abnormal follicular keratinization.¹³⁰⁴ Mild telangiectasia and slightly more chronic inflammation may be seen in the rubra variant.

The follicular keratoses that sometimes form at amputation sites are composed of large parakeratotic plugs.¹²⁹⁸

In **keratosis follicularis squamosa (Dohi)**, a disorder of follicular keratinization reported from Japan, there is increased orthokeratin adjacent to the follicle, in addition to the follicular plug of keratin.¹³⁰⁵ Clinically, there are asymptomatic small scaly patches with a central follicular plug.¹³⁰⁵ A novel locus for a familial example of this condition has been found on chromosome 7p14.3–7p12.1.¹³⁰⁶ It has been reported in association with pseudoacanthosis nigricans in an obese Japanese woman¹³⁰⁷ and with swimsuit friction.¹³⁰⁸ This variant has been successfully treated with topical tacalcitol.¹³⁰⁹

Figure 15.34 Keratosis pilaris. A keratin plug fills the infundibulum of the follicle and protrudes above the surface. (H&E)

KERATOSIS PILARIS ATROPHICANS

The term 'keratosis pilaris atrophicans' refers to a group of three related disorders in which keratosis pilaris is associated with mild perifollicular inflammation and subsequent atrophy, particularly involving the face.^{1310,1311} Differences in the location and the degree of atrophy have been used to categorize these three conditions. Fortunately, most cases cease to progress after puberty.

Treatment is usually unsuccessful. Emollients may be used. Antibiotics have no effect. Keratolytics and oral retinoids have also been used with mostly disappointing results.¹³¹¹

Keratosis pilaris atrophicans faciei (ulerythema ophryogenes)

Keratosis pilaris atrophicans faciei is manifest soon after birth by follicular papules with an erythematous halo involving the lateral part of the eyebrows.^{1312,1313} It may later involve the forehead and cheeks. Pitted scars and alopecia usually result.¹³¹³ Keratosis pilaris of the arms, buttocks, and thighs is often present. Less common clinical associations include atopy, mental retardation,¹³¹³ woolly hair,¹³¹⁴ cardiofaciocutaneous syndrome,^{1315,1316} Rubinstein-Taybi syndrome (OMIM 180849),¹³¹⁷ Cornelia de Lange syndrome (OMIM 122470),¹³¹⁸ Noonan's syndrome (OMIM 163950),¹³¹⁹⁻¹³²⁴ Bazex-Dupré-Christol syndrome (OMIM 301845),¹³²⁵ and a low serum vitamin A level.¹³¹³ Some reports suggest an autosomal dominant inheritance.¹³¹³ A gene in the 18p region may be involved.¹³²⁶ In fact, a patient with the 18p syndrome (OMIM 146390), in which there was partial monosomy of the short arm of chromosome 18, demonstrated speech delay, short stature, dysmorphism, and both keratosis pilaris and ulerythema ophryogenes.¹³²⁷

Keratosis follicularis spinulosa decalvans

Keratosis follicularis spinulosa decalvans (OMIM 308800) is another exceedingly rare condition that begins in infancy with diffuse keratosis pilaris associated with scarring alopecia of the scalp and eyebrows.¹³²⁸⁻¹³³¹ 'Moth-eaten' scarring of the cheeks usually results. Associations include atopy, acne keloidalis nuchae,¹³³² photophobia, corneal abnormalities, Down syndrome,¹³³³ palmoplantar keratoderma,¹³³³ woolly hair,¹³³⁴ and other ectodermal defects.¹³³⁵ The gene maps to Xp21.1-p22.2.¹³³⁶ There is now evidence that the X-linked disorder is caused by mutations in the *MBTPS2* gene (membrane-bound transcription factor protease, site 2) (OMIM 300294).¹³³⁷ This codes for a membrane-embedded zinc metalloprotease that activates signaling proteins involved in sterol control of transcription and endoplasmic reticulum stress response. This gene mutation has been linked to IFAP syndrome, consisting of total alopecia, ichthyosiform dermatosis, and photophobia – a disorder with an overlapping phenotype. Several families have now been reported with mutations of this gene and keratosis follicularis spinulosa decalvans.^{1337,1338} Females can be involved.¹³³⁹ Some cases are sporadic, whereas other cases appear to be autosomal dominant.¹³⁴⁰ On histological examination, there is hyperkeratosis, follicular keratotic plugging, mild perifollicular chronic inflammation, and focal scarring.¹³⁴¹ Biopsies from the scalp show a scarring alopecia with some features of folliculitis decalvans.¹³⁴² A variant with autosomal dominant inheritance and inflammation that begins at puberty has been called '*folliculitis spinulosa decalvans*'.¹³¹⁰

Treatment failure is the usual outcome. Oral isotretinoin is sometimes effective.¹³³²

Atrophoderma vermiculata

Atrophoderma vermiculata (folliculitis ulerythematosa reticulata)^{1343,1344} involves the preauricular region and cheeks.¹³⁴⁵⁻¹³⁴⁹ It may follow

Blaschko's lines.¹³⁵⁰ It develops in late childhood with the formation of horny follicular plugs that are later shed. This is followed by a reticulate atrophy with some comedones and scattered milia. Inheritance is autosomal dominant in type. Rare clinical associations include Marfan's syndrome,¹³⁵¹ leukokeratosis oris,¹³⁵² and trichoepitheliomas with basal cell carcinomas (ROMBO syndrome; see p. 805).^{1353,1354} Keratosis pilaris of the limbs is quite commonly present. A condition described in the literature as **atrophia maculosa varioliformis cutis** (OMIM 601341) affects a similar location on the cheeks,¹³⁵⁵⁻¹³⁵⁸ but there is no mention in these cases of a preceding stage with follicular plugging.¹³⁵⁵ Extrafacial involvement also occurs.¹³⁵⁹ Familial cases of this variant have been reported.¹³⁶⁰⁻¹³⁶² It appears to be autosomal dominant.¹³⁶³ A disorder of elastin has been suggested.¹³⁶⁴ Another variant has been called '**hereditary perioral pigmented follicular atrophoderma**' (OMIM 603587). It is associated with milia and epidermal cysts.¹³⁶⁵

All three conditions are regarded as congenital follicular dystrophies with abnormal keratinization of the superficial part of the follicles. A fourth condition, **erythromelanosis follicularis faciei et colli**, has minute follicular papules resulting from small keratin plugs associated with red-brown pigmentation and fine telangiectases.¹³⁶⁶⁻¹³⁷⁴ Lesions are usually confined to the face and neck, but there may be extension onto the upper trunk.¹³⁷⁵ This rare disease appears to be another follicular dystrophy but is usually not considered with the other three conditions because it lacks any atrophy. Familial cases have been reported.¹³⁷⁶⁻¹³⁷⁸ In one of these families, keratosis pilaris was also present.¹³⁷⁷ It has also been present in many of the nonfamilial cases.¹³⁷⁵

Histopathology

In all three variants of keratosis pilaris atrophicans, there is follicular hyperkeratosis with atrophy of the underlying follicle and sebaceous gland.^{1344,1379,1380} Comedones and milia may also be present.¹³⁴⁵ There is variable perifollicular fibrosis that may extend into the surrounding reticular dermis as horizontal lamellar fibrosis.¹³²⁸ The dermis may be reduced in thickness. A mild perivascular and perifollicular infiltrate of lymphocytes and histiocytes is usually present (Fig. 15.35). Keratosis follicularis spinulosa decalvans has shown eccentric epithelial atrophy (best seen in cross-sectional profiles of follicular units) and polytrichia.¹³⁸¹ In atrophoderma maculosa varioliformis cutis, there is a thin epidermis, shallow epidermal depressions, and a slight dermal decrease or fragmentation in elastic fibers in the superficial and mid dermis.¹³⁶⁴ An absence of fibrosis has been reported, and reduced or fragmented perifollicular elastic fibers can be seen in the papillary dermis.¹³⁸²

In **erythromelanosis follicularis faciei et colli**, there is follicular hyperkeratosis, mild basal pigmentation, dilatation of vessels in the papillary dermis, and a reduction in size of the hair shafts and the inner and outer root sheaths.¹³⁷⁴ A mild perivascular lymphocytic infiltrate may accompany the process.¹³⁸³

FOLLICULAR SPICULES

Follicular spicules with a horny appearance have been reported on the face of patients with multiple myeloma and cryoglobulinemia.¹³⁸⁴⁻¹³⁸⁶ The spicules are composed of eosinophilic, compact, homogeneous material that is largely the monoclonal protein of the underlying gammopathy.¹³⁸⁵ Similar spicules have been associated with intrafollicular bacteria in the absence of multiple myeloma.¹³⁸⁷ *Propionibacterium acnes* was favored as the involved organism in this case, but subsequent correspondence suggested the possibility that other organisms might be responsible, including corynebacteria or *Bacillus* species.¹³⁸⁸

Figure 15.35 Keratosis pilaris atrophicans. There are follicular hyperkeratosis, atrophy of the follicular wall, perifollicular fibrosis, and a mild perifollicular infiltrate. (H&E)

LICHEN SPINULOSUS

Lichen spinulosus is a rare dermatosis of unknown etiology characterized by follicular keratotic papules that are grouped into plaques, 2–6 cm in diameter.¹³⁸⁹ The horny spines protrude 1–2 mm above the surface. Lesions are distributed symmetrically on the extensor surfaces of the arms and legs and on the back, chest, face, and neck. Onset of the disease is in adolescence. It has been described in an HIV-positive man¹³⁹⁰ and in an elderly female with Crohn's disease.¹³⁹¹ It is commonly seen in patients with an atopic diathesis.

Treatments include emollients and/or salicylic acid,¹³⁹² topical tacalcitol,¹³⁹³ or the combination of tretinoin gel 0.04% nightly and hydroactive adhesive applications daily.¹³⁹²

Histopathology¹³⁸⁹

In lichen spinulosus, there is a keratotic plug in the follicular infundibulum as in keratosis pilaris. However, there is a heavier perifollicular infiltrate of lymphocytes in lichen spinulosus, particularly adjacent to the infundibulum of the follicle, which is often dilated. Less constant changes include perifollicular fibrosis and atrophy of the sebaceous glands.

Lichen spinulosus is best regarded as a variant of keratosis pilaris in which the lesions are more papular, a consequence of the more pronounced dermal inflammation.

PITYRIASIS FOLLICULORUM

Pityriasis folliculorum is a neglected entity resulting from the presence of numerous mites of *Demodex folliculorum* in facial hair follicles.¹³⁹⁴ Clinically, there are very small follicular scales that are dry, fine, and pale, giving a sandpaper-like texture to the skin.¹³⁹⁵ Mild erythema is present in the majority of cases. The scales correspond to the opisthosoma (caudal extremity) of the mites protruding through the follicular orifice.^{1394,1396} Mild hyperkeratosis is also seen on histology, but its contribution to the scale has not been assessed.¹³⁹⁵ There is often mild perifollicular chronic inflammation.

ROSACEA

Rosacea (acne rosacea) is a fairly common disorder of adults, involving primarily the convexities of the central face (cheeks, chin, nose, and central forehead).^{1397–1403} Rosacea may occur in other locations, but the frequency and occurrence of this are ill-defined.^{1403,1404} Rarely, children are affected.¹⁴⁰⁵ It exists in five clinical forms,^{1403,1406} although cases with overlapping features are common:

1. An erythematous, telangiectatic type, accounting for 70% of cases¹⁴⁰⁷
2. A papulopustular type
3. A granulomatous type (see p. 196)
4. A hyperplastic glandular type (phymatous rosacea) that results in irregular, bulbous enlargement of the nose – the condition known as rhinophyma¹⁴⁰⁸
5. Ocular disease.

Most cases are characterized by persistent erythema, recurrent episodes of flushing, edema, papules, and pustules. Later, telangiectasia, a burning sensation, and fibrosis occur.¹⁴⁰⁹ Crusted facial lesions associated with demodicidosis have occurred in an HIV-positive woman.¹⁴¹⁰ Central facial erythema from actinic damage should not be confused with rosacea.¹⁴¹¹ Ocular manifestations range from burning or itching to signs of conjunctival hyperemia, lid edema, rarely severe,¹⁴¹² and inflammation.¹⁴⁰³ Ocular involvement is sometimes quite severe in children.¹⁴¹³ Rosacea in adults is more common in individuals who as children had an eyelid sty.¹⁴¹⁴ It has been estimated by the National Rosacea Society in the United States that 14 million Americans have the disease.¹⁴¹⁴

Rosacea has an equal sex incidence, but the median age of presentation in males is approximately a decade later (59 years) compared to females (48 years).¹⁴⁰⁷ It has occurred in one of monozygotic twins.¹⁴¹⁵ Severe rosacea developed for the first time in an elderly male coincident with the diagnosis of a recurrence of his colon cancer.¹⁴¹⁶ **Idiopathic facial aseptic granuloma** is a disease of childhood typically manifesting as painless erythematous nodules of the cheeks. Its histopathologic image and association with chalazia suggest that it may be a form of granulomatous rosacea.¹⁴¹⁷

Although the vast majority of phymatous lesions occur on the nose (rhinophyma), they may also occur at other sites. Lesions located lateral to the nasolabial fold,¹⁴¹⁸ or involving the chin (gnathophyma),^{1419,1420} or the ear (otophyma) have been reported.¹⁴²¹ Rhinophyma has been reported in an adolescent male.¹⁴²²

Rosacea is a difficult entity to classify not only because its pathogenesis is poorly understood but also because of the broad spectrum of histopathological changes found.¹⁴²³ Rosacea has been variously regarded as a folliculitis, a sebaceous gland disorder, a response to

overabundant *Demodex* mites, and a functional disorder of superficial dermal blood vessels associated with prominent flushing.^{1424,1425} The last of these possibilities is currently the most favored, although some of the evidence supporting it is somewhat circumstantial.^{1401,1426,1427} Vasodilator drugs may also exacerbate rosacea.¹⁴²⁸ Although there is enhanced skin blood flow in papulopustular rosacea, the increase is not significant in the erythematotelangiectatic variant.¹⁴²⁹ Neoangiogenesis occurs in this latter variant.¹⁴³⁰ Lymphatics are increased in lesional skin from an early stage, even in the absence of edema.¹⁴³¹ *Demodex* mites may be increased secondary to these vascular changes.^{1432,1433} *Demodex* mites have been regarded as a cofactor rather than the cause of rosacea,¹⁴³⁴ even though rosacea-like eruptions can be seen in response to heavy local infestations by *D. folliculorum* (rosacea-like demodicidosis; see p. 769).^{1394,1435} Recently, antigenic proteins from a bacterium, *Bacillus oleroni*, isolated from *D. folliculorum* in a patient with papulopustular rosacea, were found to have the potential to stimulate an inflammatory response in rosacea patients.¹⁴³⁶ On the other hand, there is evidence that microorganisms are neither the primary factor nor a necessary factor in the pathogenesis of rosacea.¹⁴³⁷ Rosacea-like eruptions may also occur following the topical application of potent fluorinated steroids,^{1438–1440} the use of a halogenated steroid nasal spray,¹⁴⁴¹ and the application of pimecrolimus.¹⁴⁴² A florid papulopustular eruption with a spiny filiform hyperkeratosis has developed during therapy with the multikinase inhibitor sorafenib.¹⁴⁴³ Acne rosacea has been reported in patients with HIV infection.¹⁴⁴⁴ There has been considerable interest in the role of *Helicobacter pylori* in the etiology of rosacea;^{1445–1449} however, controlled trials offer no support for this association.^{1450–1452} It is likely that the treatment used for *H. pylori* is beneficial for rosacea.^{1453–1458} A rosacea-like eruption has also occurred with *Candida albicans* infection.¹⁴⁵⁹ Investigations into the mechanism of rosacea have shown elevated levels of TLR2 in the epidermis from rosacea patients compared to normal controls. Expression of TLR2 leads to increased kallikrein-5 production and protease activity, which may play a role in the inflammation associated with this disease.¹⁴⁶⁰

Perioral dermatitis (see p. 197) is possibly a related entity.^{1461–1466} It is characterized by burning, non-itchy, perioral erythema and papules usually associated with severe discomfort.^{1467,1468} It has been regarded by some as a subtype of rosacea in atopic patients.¹⁴⁶⁹ It may follow corticosteroid therapy.¹⁴⁷⁰ **Periocular dermatitis** is considered to have a similar pathomechanism as perioral dermatitis.¹⁴⁷¹ Sometimes rosacea will present with periorbital edema.¹⁴⁷² This feature should not be confused with periocular dermatitis. Griffiths has drawn attention to a group of patients with lesions resembling what has been called perioral dermatitis which he calls the **MARSH syndrome**, combining as it does *melasma*, *acne*, *rosacea*, *seborrheic eczema*, and *hirsutism*.¹⁴⁷³

Treatments include topical metronidazole,¹⁴⁰⁹ azelaic acid,¹⁴⁷⁴ azithromycin, minocycline,¹⁴⁷⁵ pimecrolimus 1% cream,¹⁴⁷⁶ oxymetazoline for erythema and flushing,¹⁴⁷⁷ lasers for persistent telangiectasia, intense pulsed light,¹⁴⁷⁸ photodynamic therapy,¹⁴⁷⁹ and isotretinoin for mild to moderate rhinophyma; late stages of the latter require surgery.¹⁴⁸⁰

Histopathology¹⁴⁸¹

Rosacea is characterized by a combination of several histopathological features. Sometimes the histopathological changes are nondiagnostic.¹⁴⁸² In the erythematous–telangiectatic group, there is telangiectasia, sometimes prominent, of superficial dermal vessels (Fig. 15.36). There is a perivascular infiltrate of lymphocytes, usually mild to moderate in intensity. A small number of plasma cells are usually present and are an important clue to the diagnosis. Inconstant features include mild dermal edema, solar elastosis, and mild perifolliculitis. The papulopustular lesions have a more pronounced

Figure 15.36 Rosacea. A perivascular and perifollicular infiltrate of lymphocytes and plasma cells is present. Several *Demodex* mites are present in the hair follicle. (H&E)

inflammatory cell infiltrate that is both perivascular and peripilar, involving the superficial and mid dermis. The infiltrate may include a few neutrophils as well as lymphocytes and plasma cells. Active pustular lesions show a superficial folliculitis, whereas in older lesions a granulomatous perifolliculitis is often present. Folliculitis and perifolliculitis, with infiltrates that feature lymphocytes, plasma cells, and granulomas, are characteristic of idiopathic facial aseptic granuloma.¹⁴¹⁷ Keratotic follicular plugging, but not comedones, may be present. *Demodex* mites are present in 20–50% of cases. The granulomatous form¹⁴⁸³ is usually characterized by a tuberculoid reaction, often in the vicinity of damaged hair follicles (see p. 196). Necrosis, resembling caseation, was present in 11% of patients in one series (Fig. 15.37).¹⁴⁸⁴

Sebaceous gland hypertrophy and scattered follicular plugging are present in most cases of rhinophyma (Fig. 15.38).¹⁴⁸⁵ In the less common fibrous variant of rhinophyma, there is telangiectasia, diffuse dermal fibrosis with abundant mucin, a virtual absence of pilosebaceous structures, and an increase in factor XIIIa-positive cells in the dermis.^{1486,1487} Telangiectasia of superficial dermal vessels is also quite common – a feature that is not present in senile sebaceous gland hyperplasia.

Figure 15.37 Granulomatous rosacea. This florid case has extensive necrosis resembling caseation necrosis. (H&E)

Figure 15.38 Rhinophyma. There is sebaceous gland hyperplasia in this shave biopsy. (H&E)

Demodex mites may be present in the pilosebaceous follicles. Inconstant features include solar elastosis, dilatation of follicles, focal folliculitis, and perifolliculitis. Sometimes, finger-like acanthotic downgrowths extend from the epidermis and follicular walls.¹⁴⁸⁵ The infiltrate of lymphocytes and plasma cells around superficial vessels varies from sparse to moderately heavy in intensity.

Direct immunofluorescence has demonstrated the presence of immunoglobulins and complement in the region of the dermoepidermal junction in some cases.^{1488,1489} Immunoperoxidase stains show increased expression of vascular endothelial growth factor (VEGF), CD31, and the lymphatic marker D2-40.¹⁴³¹ MMP-9 is increased in patients with rosacea and *D. folliculorum* mites, raising the possibility of a pathogenetic link.¹⁴⁹⁰

Differential diagnosis

Erythema associated with rosacea can be histopathologically subtle, resembling other forms of telangiectasia or urticarial tissue reactions. Inflammatory papules and pustules have features similar to those of other forms of folliculitis. In acne vulgaris, comedones are the hallmarks of the disease, whereas the microcomedones of rosacea are not

as prominent. As noted previously, perioral dermatitis has overlapping features and is regarded by some as a rosacea variant. Granulomatous rosacea can resemble lupus vulgaris, which is also, in part, a folliculocentric disease; the latter can be diagnosed by evaluations for other manifestations of tuberculosis or with PCR studies. Caseous necrosis in association with perifollicular granulomas has been seen in rosacea and is a hallmark of lupus miliaris disseminatus faciei; the relationship of these conditions has been the subject of debate. Naked tubercles in granulomatous rosacea can be confused with sarcoidosis, and there can also be clinical overlap of the two diseases. The glandular hyperplastic form of rosacea is often clinically apparent, but facial biopsies of older adults frequently show prominent sebaceous glands as an incidental finding.

PYODERMA FACIALE (ROSACEA FULMINANS)

Pyoderma faciale is a rare disorder, now interpreted as a fulminant form of rosacea.^{1491–1493} The term ‘rosacea fulminans’ has been suggested as a more appropriate designation.¹⁴⁹⁴ It is characterized by the sudden onset of confluent nodules and papulopustules on the face in women who are usually in their twenties.¹⁴⁹¹ Purulent material drains from many sinuses, which may be interconnecting. Pyoderma faciale may sometimes occur in association with inflammatory bowel disease^{1494–1496} and erythema nodosum.¹⁴⁹⁷ There have been examples accompanied by vulvar pustulation¹⁴⁹⁸ and ocular involvement,¹⁴⁹⁹ including ocular perforation.¹⁵⁰⁰ Both commencement in pregnancy and postpartum onset have been reported.^{1501,1502} It has also occurred in a woman taking high-dose vitamin B supplements, the cessation of which led to improvement.¹⁵⁰³

Conventional rosacea therapy is not effective. Short-term systemic corticosteroids usually followed by oral retinoids have been used.¹⁵⁰⁴ Topical corticosteroids are applied to lesional skin. Dapsone has been effective when this listed treatment failed.¹⁵⁰⁵

Histopathology¹⁴⁹²

Few cases have been biopsied. There is usually a heavy dermal infiltrate of neutrophils, lymphocytes, and epithelioid cells with occasional granulomas with multinucleate giant cells. Perifollicular abscesses and sinus formation may be present, sometimes associated with pseudoepitheliomatous hyperplasia.¹⁴⁹⁸

SQUAMOUS METAPLASIA OF SEBACEOUS GLANDS

Squamous metaplasia has been reported at sites of pressure following cardiac surgery.¹⁵⁰⁶ Ischemia appears to play a major role. The changes commence in the germinative outer layer of the sebaceous gland and advance in a centripetal manner, replacing sebocytes.¹⁵⁰⁶

NEUTROPHILIC SEBACEOUS ADENITIS

The term ‘neutrophilic sebaceous adenitis’ has been used for the circinate plaques on the face of a teenage male that were characterized histologically by neutrophilic infiltration of the sebaceous glands.¹⁵⁰⁷ A case with similar clinical features, including spontaneous healing, has since been reported.¹⁵⁰⁸ It differed from the original case by having few neutrophils and many lymphocytes infiltrating sebaceous glands. This might have resulted from the age of the lesion, which had been present for 2 months at the time of the biopsy.

A **sebotropic drug reaction** has been reported following the ingestion of kava-kava extract, used as an antidepressant therapy.¹⁵⁰⁹ The extract contains kavapyrones, which are lipophilic. A dense

lymphocytic infiltrate disrupted sebaceous glands, which were partly necrotic.¹⁵⁰⁹

A sebaceous adenitis (sebaceitis) can also be seen in herpes folliculitis.

FOLLICULAR SEBACEOUS CASTS

Multiple spiky lesions have been reported in the nasolabial region following isotretinoin therapy for acne. Microscopy revealed cast-like accumulations of holocrine secretion, derived from sebaceous glands (sebaceous casts), on the surface of the stratum corneum.¹⁵¹⁰ Subsequent correspondence suggested that this change had been reported earlier as follicular filaments (follicular casts).¹⁵¹¹

APOCRINE DISORDERS

The normal apocrine gland

Apocrine glands are found regularly in the axilla, anogenital region, the areola and nipple of the female breast, the eyelids (Moll's glands), and the external auditory canal. They are sometimes found in the skin of the scalp and the face. Apocrine glands are derived from the primary epithelial germ along with the hair follicle and sebaceous gland.

The apocrine gland consists of a secretory portion in the deep dermis or subcutis and a short duct that enters into the infundibulum of the hair follicle, above the entry of the sebaceous duct. Apocrine glands have a variable appearance in tissue sections, reflecting the functional state of the gland; secretions are stored in the gland. Both a 'budding type' (apocrine secretion) and a merocrine type of cytoplasmic secretion occur.

A detailed study of axillary skin failed to detect any glands resembling the apoeccrine gland.¹⁵¹² This has pathogenetic implications for axillary hyperhidrosis because the higher output of these glands has been presumed to be of importance in hyperhidrosis.¹⁵¹²

Disorders of apocrine glands

Diseases of the apocrine glands are exceedingly uncommon. Only apocrine miliaria and apocrine chromhidrosis have dermatopathological interest (see later).¹⁵¹³ Mucinous metaplasia of an apocrine duct is mentioned here, in the discussion of its eccrine equivalent.

APOCRINE MILIARIA (FOX-FORDYCE DISEASE)

Apocrine miliaria (Fox-Fordyce disease) presents as a chronic papular eruption limited to areas bearing apocrine glands.¹⁵¹⁴ The papules are small, infundibulocentric, sometimes with a keratotic plug in the center of the papule, and sometimes with a yellow cast.¹⁴¹⁸ The axillae are most commonly involved, but more than one site may be involved simultaneously.^{1515,1516} There is intense pruritus that is sometimes intermittent.^{1517,1518} The condition affects, almost exclusively, young adult females, although males are not exempt.^{1519,1520} Axillary lesions have occasionally resulted from the prolonged use of topical antiperspirants.¹⁵²¹ It has been reported in two patients with Turner's syndrome under treatment with growth hormone.¹⁵²² Lesions have also been induced by laser hair removal therapy.¹⁵²³

Apocrine miliaria results from rupture of the intraepidermal portion of the apocrine duct. This appears to result from keratotic plugging of the duct producing an outflow obstruction. A second type has been postulated involving apoeccrine glands.¹⁵¹⁶ In these cases, the intraepidermal apoeccrine sweat duct is said to be blocked by apoeccrine secretory cells that have detached.¹⁵¹⁶

Numerous treatments have been used, including topical, systemic, and intralesional corticosteroids; UV phototherapy; topical retinoids;

Figure 15.39 Apocrine miliaria (Fox-Fordyce disease). There is spongiosis at the point of entry of the apocrine duct. (H&E)

lasers; and plastic surgery. Liposuction-assisted curettage has also been used.¹⁵²⁴ Recently, 1% pimecrolimus cream was used. Lesions cleared within 1 week, but maintenance therapy was continued.¹⁵²⁵

Histopathology^{1514,1526}

Serial sections are often required to demonstrate the spongiosis and spongiotic vesiculation of the follicular infundibulum adjacent to the point of entry of the apocrine duct (Fig. 15.39). A keratotic plug is sometimes seen above this area.^{1517,1526} A retention vesicle may be difficult to find.¹⁵²⁷ There is an associated mild to moderate inflammatory cell infiltrate that may contain some neutrophils as well as chronic inflammatory cells. Additional features described by Böer in a comprehensive study of this entity include vacuolar alteration at the dermoepithelial junction of infundibula, dyskeratotic cells scattered in infundibula, and parakeratosis resembling cornoid lamellation within an orthokeratotic plug filling a dilated infundibulum.¹⁴¹⁸ These findings were not confirmed in a subsequent study by Bormate, LeBoit, and McCalmont.¹⁵²⁷ They did find perifollicular foam cells as a relatively consistent and distinctive feature (Fig. 15.40).¹⁵²⁷ The nature of the foamy material has been clarified in recent studies. Both apocrine secretion and the foam cell cytoplasm were found to be PAS positive.¹⁵²⁸ Furthermore, there is positive staining of both the xanthomatous infiltrate and spongiotic foci of involved follicular epithelia with anti-human milk fat globulin.¹⁵²⁹

Transverse sections, as used in the assessment of alopecias, demonstrate diagnostic features more effectively than conventional sections.¹⁵³⁰

APOCRINE CHROMHIDROSIS

Chromhidrosis refers to the production of colored sweat by apocrine or eccrine sweat glands.¹⁵³¹⁻¹⁵³³ Slight coloration of apocrine sweat is not uncommon. Pseudochromhidrosis refers to coloration of sweat on the surface of the skin by exogenous dyes or chromogenic organisms.^{1534,1535} Blue pseudochromhidrosis has followed the use of combination therapy consisting of a proton pump inhibitor and a type 2 histamine antagonist.¹⁵³⁶ In one case of blue sweat, the etiology was never determined.¹⁵³⁷ Successful treatment with botulinum toxin A has been reported.¹⁵³⁸ Bromhidrosis is a clinical disorder characterized by excessive or foul axillary odor resulting from the interaction of apocrine sweat and microorganisms. It has been treated by superficial liposuction with curettage.¹⁵³⁹

Figure 15.40 Fox-Fordyce disease. Portions of a keratotic plug and spongiosis of follicular epithelium can be observed. In addition, foam cells are present adjacent to the follicle (arrow). (H&E)

Histopathology

Orange-brown cytoplasmic granules, predominantly in an apical location, are present in apocrine sweat glands in apocrine chromhidrosis (Fig. 15.41). The pigment may not always be lipofuscin, as originally believed.¹⁵³¹

ECCRINE DISORDERS

The normal eccrine gland

The eccrine gland is derived from the primitive epidermal ridge. It is composed of a secretory coil (glandular portion) that leads into a coiled proximal duct and then a straight duct that eventually passes through the epidermis. The secretory coil is composed of glycogen-containing clear cells and dark cells that are surrounded by a layer of myoepithelial cells, outside which is the basement membrane. Eccrine glands are most numerous on the sole of the foot.

Eccrine sweat consists predominantly of water. The salt content of the secretions is reduced in the proximal duct, resulting in the release

Figure 15.41 Apocrine chromhidrosis. Granular material is present in the cytoplasm of some apocrine cells. (H&E)

of hypotonic sweat on the skin surface. Sweating dissipates body heat by means of surface evaporation.

Disorders of eccrine glands

Functional disorders of the sweat gland, particularly hyperhidrosis (excessive sweating), are an important clinical problem.¹⁵⁴⁰ The prevalence of hyperhidrosis in the United States is estimated to be 2.8%, and half of this population has axillary hyperhidrosis.¹⁵⁴¹ Hyperhidrosis is not related to any morphological changes in the sweat glands.¹⁵⁴²⁻¹⁵⁴⁸ Localized unilateral hyperhidrosis has been reported. It responds to injections of botulinum toxin type A,^{1549,1550} as does axillary hyperhidrosis.¹⁵⁵¹⁻¹⁵⁵³ It may also be treated by selective sweat gland removal.¹⁵⁵⁴ Botulinum toxin iontophoresis has been used in the treatment of palmar hyperhidrosis.^{1555,1556} Botulinum toxin appears to reduce the size of the eccrine gland lumen.¹⁵⁵⁶ Very mild inflammation of the eccrine coils is seen in **granulosis rubra nasi**, a rare condition with onset in childhood characterized by excessive sweating of the central face, including the nose, with superimposed erythema.¹⁵⁵⁷ Many cases resolve spontaneously at puberty. Hyperhidrosis is not considered further. Anhidrosis is best known as a component of ectodermal dysplasia (see p. 316),¹⁵⁵⁸ but a rare acquired form has been reported. In one such case, an eosinophilic, PAS-positive plug occluded the acrosyringium.¹⁵⁵⁹ Obstruction of the eccrine duct produces small vesicular lesions known as miliaria (see p. 108). Eccrine glands may be absent in some types of ectodermal dysplasia and following irradiation of the skin. Horizontal sections can be used to assess eccrine glands.¹⁵⁶⁰

Seven histopathological entities are considered: eccrine duct hyperplasia, syringolymphoid hyperplasia, eccrine metaplasias, neutrophilic eccrine hidradenitis, palmoplantar eccrine hidradenitis, sweat gland necrosis, and hematidrosis.

ECCRINE DUCT HYPERPLASIA

The proliferation of eccrine ducts is not a distinct clinical entity but a histological reaction pattern that can be seen in a variety of circumstances.¹⁵⁶¹ The best documented of these is in keratoacanthomas,¹⁵⁶² in which the epithelium of the lower duct and of the secretory coil may show atypical hyperplasia or squamous metaplasia (see later). Rarely, eccrine ducts are prominent and presumably hyperplastic, overlying an intradermal nevus or adjacent to epithelial

tumors on the dorsum of the hand and on the lower leg.¹⁵⁶³ Branching ducts can also be seen in these circumstances. Some of these cases have been included, incorrectly, as variants of syringofibroadenoma (see p. 942).

Eruptive lesions resulting from eccrine duct hyperplasia have been reported following the use of benoxaprofen (Opren®), a drug that has been withdrawn from the market.¹⁵⁶⁴

Guitart *et al.* believe that some cases of ‘eruptive syringoma’ are not neoplasms but, rather, examples of reactive ductal proliferation of eccrine glands.¹⁵⁶⁵ They may follow autoimmune destruction of the eccrine duct (see p. 935). Tortuous hyperplasia of ducts can accompany some inflammatory processes of the skin, such as eczema. Inflammation of the superficial portions of the duct are seen in early cases of this phenomenon.¹⁵⁶⁵

SYRINGOLYMPHOID HYPERPLASIA

Hyperplastic sweat ducts sleeved by a dense lymphocytic infiltrate (*syringolymphoid hyperplasia*) have been reported in patients, predominantly males, with multiple reddish-brown papules, forming a plaque of alopecia (Fig. 15.42).^{1566–1569} The lesions develop over several years.¹⁵⁷⁰ Anhidrosis is often present.¹⁵⁷¹ Although this condition can be idiopathic, most cases represent a syringotropic cutaneous T-cell lymphoma.^{1572,1573} The infiltrate is often clonal, but other features of a cutaneous T-cell lymphoma are often lacking. The cells are usually CD4⁺⁺, but CD7 may not be expressed.¹⁵⁷⁰ Proliferation of ducts, without any inflammation, has been seen in a biopsy from the scalp of a patient with alopecia areata.¹⁵⁷⁴

Lymphocytic autoimmune hidradenitis is an exceedingly rare manifestation of Sjögren’s syndrome in which an infiltrate of mature lymphocytes forms a sleeve around the eccrine glands. The sweat gland epithelium may be hyperplastic,¹⁵⁷⁵ resembling eccrine syringolymphoid hyperplasia, or it can be atrophic.¹⁵⁷⁶

ECCRINE METAPLASIAS

Clear cell metaplasia, not due to glycogen or lipid, is occasionally an incidental finding in eccrine glands and, to a lesser extent, eccrine ducts.¹⁵⁷⁷ This and other minor histological variations in the morphol-

Figure 15.42 Syringolymphoid hyperplasia. A hyperplastic sweat duct is sleeved by a dense lymphocytic infiltrate. (H&E)

ogy of the eccrine apparatus have been reviewed on several occasions.^{42,1578} Clear cell change was present in the eccrine ducts and to a lesser extent in the eccrine glands in a patient who presented with a miliaria-like papular eruption of the extremities.¹⁵⁷⁹ The term ‘**eruptive clear cell hamartoma**’ of sweat ducts was used.¹⁵⁷⁹ A similar case has been reported as ‘papular clear cell hyperplasia of the eccrine duct in a diabetic’.¹⁵⁸⁰

Granular parakeratosis was confined predominantly to eccrine ostia in one case.¹⁵⁸¹ Granular parakeratosis is considered on page 319.

Squamous metaplasia of glandular and ductal epithelium (*squamous syringometaplasia*) is a not-uncommon histological finding in areas of ischemia and adjacent to ulcers or healing surgical wounds,^{1582,1583} it may follow irradiation,^{1584,1585} burns,¹⁵⁸⁶ cryotherapy or curettage,^{1587,1588} or present as a primary process.¹⁵⁸⁹ This change has also been reported in pyoderma gangrenosum, annular elastolytic granuloma,¹⁵⁹⁰ systemic lupus erythematosus,¹⁵⁹¹ linear scleroderma,¹⁵⁹² herpetic infection in HIV-positive patients,^{1593,1594} cytomegalovirus infection,^{1595,1596} phytophotodermatitis,¹⁵⁹⁷ lobular panniculitis,¹⁵⁹⁸ and in association with ductal eccrine carcinoma.¹⁵⁹⁹ Clinically, it may mimic a herpetic infection.¹⁶⁰⁰ The occurrence of squamous metaplasia in patients receiving chemotherapy for various malignant tumors^{1601–1606} has led to the suggestion that squamous syringometaplasia is at the non-inflammatory end of the spectrum of eccrine gland reactions induced by chemotherapy, and neutrophilic eccrine hidradenitis (see later) is at the inflammatory end.¹⁶⁰² It has also been induced by the tyrosine kinase inhibitors imatinib¹⁶⁰⁷ and sunitinib.¹⁶⁰⁸ Squamous syringometaplasia may simulate squamous cell carcinoma because of the islands of atypical squamous epithelium in the dermis, but careful inspection will show a normal architectural pattern of sweat glands and the presence of a lumen with a hyaline inner cuticle. This condition is analogous to necrotizing sialometaplasia, an entity found in minor salivary glands.¹⁶⁰⁹

Mucinous syringometaplasia is a rare entity that presents as a verruca-like lesion on the sole of the foot or finger or as an ulcerated nodule in other sites.^{1610–1612} Histologically, there is usually a shallow depression in the epidermis with one or several duct-like structures leading into the invagination. Deep invaginations have been reported.¹⁶¹³ The ducts and portions of the surface epithelium are lined by low columnar, mucin-containing cells admixed with squamous epithelium (Fig. 15.43). The goblet cells in one reported case also extended into the sweat glands in the deep dermis.¹⁶¹⁴ The staining characteristics suggest that a sialomucin is present. Positive staining for carcinoembryonic antigen (CEA), epithelial membrane antigen, and CAM 5.2 has been reported.¹⁶¹⁰ The adjacent dermis contains a variable chronic inflammatory cell infiltrate with lymphocytes and plasma cells.

Four other mucinous lesions of epithelium have been reported. **Eccrine ductal mucinosis** refers to the accumulation of mucin between the cells of the outer layers of the eccrine duct.¹⁶¹⁵ It has been reported in a patient with HIV infection.¹⁶¹⁵ **Benign mucinous metaplasia** affects the surface epithelium, which is replaced by mucin-containing cells and goblet cells. It has been reported on the vulva¹⁶¹⁶ and the penis.¹⁶¹⁷ It presents as an erythematous plaque. No ducts are involved as in mucinous syringometaplasia (discussed previously). In **mucinous metaplasia of eccrine secretory coils**, the metaplasia is situated in the deep dermis with no surface connection. As the name indicates, it involves the secretory units. In the case reported, there was an adjacent apocrine cystadenoma.¹⁶¹⁸ **Mucinous metaplasia of an apocrine duct** refers to a case in which a duct of presumptive apocrine origin was involved by this metaplastic process.¹⁶¹⁹

NEUTROPHILIC EC CRINE HIDRADENITIS

Neutrophilic eccrine hidradenitis is a rare complication of induction chemotherapy used in the treatment of an underlying cancer.^{1583,1620–1623} The first reports concerned patients with acute myelogenous

Figure 15.43 Mucinous syringometaplasia. Mucin-containing cells are admixed with squamous epithelium in the duct-like structure that enters the epidermis from below. (H&E)

leukemia receiving cytarabine therapy,^{1620,1624} but other cancers^{1625–1629} and other agents^{1626,1630} have now been implicated, including cetuximab¹⁶³¹ and carbamazepine,¹⁶³² as has granulocyte colony-stimulating factor (G-CSF).¹⁶³³ It has been reported in patients with leukemia, unassociated with chemotherapy.^{1634,1635} In one of these cases, acetaminophen (paracetamol) was implicated.¹⁶³⁶ It has also been reported in HIV-infected patients^{1637–1639} and also in Behçet's disease.¹⁶⁴⁰ It is rarely due to infection. *Serratia marcescens* has been implicated in two of these infective cases,¹⁶⁴¹ and *Nocardia asteroides* has also been involved in another case.¹⁶⁴² Clinically, there are plaques and nodules, often on the trunk. Involvement of the ears and circumferential involvement of the breasts have been reported.^{1643,1644} This entity may masquerade as a facial cellulitis.¹⁶⁴⁵ Lesions are usually asymptomatic, but pruritic lesions sometimes develop.¹⁶⁴⁰ The lesions may resolve after 2 or 3 weeks.

Histopathology^{1620,1624–1626}

There is an infiltrate of neutrophils around and within the eccrine secretory coils, associated with vacuolar degeneration and even

Figure 15.44 (A) Eccrine hidradenitis. (B) Neutrophils surround and engulf the eccrine secretory glands. (H&E)

necrosis of the secretory epithelium (**Fig. 15.44**).¹⁶²⁹ The neutrophilic infiltrate may be mild in patients with a neutropenia.¹⁶⁴⁶ Squamous metaplasia is sometimes present. There may be edema and mucinous change in the loose connective tissue and fat surrounding the coils. Apocrine involvement has also been reported.¹⁶⁴⁷ An epidermal lichenoid tissue reaction with prominent basal vacuolar change is sometimes present as well.

PALMOPLANTAR ECCRINE HIDRADENITIS

Palmoplantar eccrine hidradenitis is closely related to neutrophilic eccrine hidradenitis.^{1648–1650} It was originally described in children presenting with tender, erythematous plantar nodules (idiopathic plantar hidradenitis);¹⁶⁴⁸ patients with palmoplantar involvement and exclusive palmar involvement have since been reported.^{1649,1651–1653} The lesions usually resolve in 2–4 weeks without treatment;^{1648,1654} recurrences and longer duration of the lesions have been reported.^{1649,1653,1655} It has been suggested that plantar hidradenitis might be induced by exposure to a wet and cold milieu.¹⁶⁵⁶ It has followed trauma and associated exposure to aluminum dust.¹⁶⁵³ Certainly, there is a seasonality in its occurrence,¹⁶⁵¹ with a predilection for summer months.¹⁶⁵⁷

Histopathology

Dense neutrophilic infiltrates, localized to the eccrine units, are present. The infiltrate involves primarily the eccrine duct with partial sparing of the secretory segment. In contrast to neutrophilic eccrine hidradenitis (discussed previously), squamous metaplasia is usually absent.¹⁶⁴⁸ IL-8 was not detected in the skin in one series.¹⁶⁵⁷

SWEAT GLAND NECROSIS

Sweat gland necrosis occurs in association with vesiculobullous skin lesions in patients with drug-induced and carbon monoxide-induced coma. This entity is discussed in further detail on page 186.

HEMATIDROSIS

Hematidrosis, the excretion of bloody sweat, is an extremely rare phenomenon. A related phenomenon is hemolacria or bloody tears.¹⁶⁵⁸ There is no satisfactory explanation for most of the reported cases. This account is prompted by the report of a case with accompanying histology.¹⁶⁵⁹ The adolescent female had recurrent episodes of bloody

sweat from her palms, soles, arms, legs, and occasionally her trunk. A biopsy showed blood-filled spaces that opened into ‘follicular canals or on to the skin surface’. The origin of these vascular lakes was not satisfactorily explained.¹⁶⁵⁹

VESTIBULAR GLAND DISORDERS

The vulvar vestibular mucosa undergoes subtle changes during the menstrual cycle, as do other parts of the genital mucosa. Changes also occur in women taking the oral contraceptive pill.¹⁶⁶⁰ The pill may result in an erythematous and hypersensitive vestibular mucosa associated with superficial dyspareunia.¹⁶⁶⁰

VULVAR VESTIBULITIS

Vulvar vestibulitis (vestibular adenitis) is characterized by dyspareunia, point tenderness localized to the vulvar vestibule, and varying degrees of erythema. There appears to be no association with human papillomavirus infection, as once thought.¹⁶⁶¹ Vulvar vestibulitis is just one of many causes of vulvodynia.¹⁶⁶² The vulvar vestibulitis syndrome has been renamed vestibulodynia.¹⁶⁶⁰

Histopathology¹⁶⁶¹

There is a chronic inflammatory cell infiltrate, composed predominantly of lymphocytes but with some plasma cells, involving mainly the mucosal lamina propria and periglandular/periductal connective tissue. Squamous metaplasia of the minor vestibular glands is a consistent feature.¹⁶⁶³ An adenomatous proliferation of mucous glands was present in one case with a similar clinical presentation.¹⁶⁶¹

INTRODUCTION

A *cyst* is an enclosed space or abnormal sac within a tissue, usually containing fluid or semisolid matter and lined by epithelium. Cysts are usually classified on the basis of their pathogenesis. In the skin, the most important cysts are derived from the dermal appendages as retention cysts. The developmental cysts, which result from the persistence of vestigial remnants, are much less common. The term ‘pseudocyst’ is sometimes applied to cyst-like structures without an epithelial lining. The important histological features of the various cutaneous cysts are shown in [Table 16.1](#). A detailed review of dermal cysts was published in 2007.¹

A *sinus* is a tract or recess lined by epithelium or granulation tissue. In contrast, a cutaneous *pit* is a small depression in the epidermal surface.

The frontal mucocele that presented as a subcutaneous cyst on the forehead defies classification.²

Table 16.1 Histological features of various cysts	
Type	Important features
Epidermal	Epidermal keratinization; keratohyaline granules
HPV-related	Either intracytoplasmic inclusions and vacuolar keratinous changes or verrucous lining (papillated and/or digitated) with hypergranulosis
Trichilemmal	Trichilemmal keratinization; cholesterol clefts; sometimes calcification
Onycholemmal	Cysts of nail bed, no granular layer; contain onycholemmal keratin and calcification
Hybrid	Outer epidermal and inner trichilemmal keratinization; other combinations may occur
Hair matrix	Basaloid cells with luminal squamous maturation
Cystic panfolliculoma	Infundibular lining; basaloid germinative cells, bulbs, matrical, and trichohyalin differentiation
Pigmented follicular	Epidermal-like; luminal pigmented hairs
Cutaneous keratocyst	Corrugated configuration; no granular layer; may contain vellus hairs
Vellus	Multiple; epidermal-like; luminal vellus hairs
Steatocystoma	Multiple; sebaceous glands in and adjoining wall; may contain vellus hairs
Milium	Small epidermal cyst with thinner wall
Comedonal cyst	Cystic hair follicle with keratinous material; open or closed
Eccrine hidrocystoma	Two layers of cuboidal epithelium
Apocrine cystadenoma	Columnar cells with decapitation secretion; basal myoepithelial cells
Bronchogenic	Mostly midline; respiratory epithelial lining; sometimes smooth muscle and mucous glands
Branchial	Lateral neck; stratified squamous and inner respiratory epithelial lining; heavy lymphoid tissue in wall
Thymic	Respiratory and/or squamous lining; Hassall's corpuscles in wall
Cutaneous ciliated	Lower limb of females; ciliated columnar or cuboidal lining
Median raphe	Ventral surface of penis; pseudostratified columnar epithelium
Dermoid	Periorbital or midline; epidermal-like with attached pilosebaceous structures; sometimes smooth muscle in the wall

APPENDAGEAL CYSTS

EPIDERMAL (INFUNDIBULAR) CYST

Epidermal cysts are solitary, slowly growing cysts with a predilection for the trunk, neck, and face. They measure 1–4 cm or more in diameter, although larger variants have been reported.^{3,4} A giant cyst is one more than 5 cm in diameter.⁵ Multilocular giant cysts also occur.⁶ Epidermal cysts are usually located in the mid and lower dermis, but they do not shell out like the trichilemmal cyst. There is often a surface punctum.

They are thought to be derived from the pilosebaceous follicle, but in non-hair-bearing skin, they may arise from implantation of the epidermis,⁷ particularly on the palms and soles^{8,9} and in the subungual region.^{10,11} Implantation of epidermis is the likely mechanism involved in the formation of the extremely rare midline cysts of the scalp, which are present at birth.¹² Eccrine ducts may rarely give rise to epidermal cysts,^{13,14} particularly on the soles,¹⁵ in association with HPV-60 infection (see later). Epidermal cysts have also developed following chronic dermabrasion¹⁶ and photodynamic therapy¹⁷ and at the site of healed herpes zoster.¹⁸ Multiple cysts may be found, sometimes in association with Gardner's syndrome.^{19–23} They have been reported in mycosis fungoides.²⁴

Epidermal cysts may become infected, and this may be followed by rupture of the cyst, usually into the dermis. Rupture can be detected by ultrasonography.²⁵ Cultures of infected cysts have grown *Staphylococcus aureus* or a mixed growth of organisms.^{26,27} However, a more recent study has shown that the microbiological milieu of inflamed and uninfamed cysts is the same, calling into question the traditional view that bacterial infection is the etiology of the inflammation in epidermal cysts.²⁸ There is a predominance of anaerobes in infected cysts in the genital and perineal regions.²⁶ Secondary infection by a dermatophyte has been reported,²⁹ and an epidermal cyst infected by *Entamoeba histolytica* has also been described.³⁰

Histopathology

Epidermal cysts are lined by stratified squamous epithelium showing epidermal keratinization – that is, the formation of keratohyaline granules and flattened surface epithelium ([Fig. 16.1](#)). As such, they are thought to be derived from or to mimic the infundibular portion of the hair follicle. Rupture of a non-inflamed cyst will produce a localized foreign body granulomatous reaction in the adjacent dermis, whereas rupture of an inflamed cyst usually results in a heavy inflammatory cell infiltrate in the adjacent dermis, sometimes with destruction of the cyst wall in the process. Fibrosis usually occurs subsequently. A scrotal epidermal cyst with calcification was found to have infiltration of its wall by eosinophils.³¹

The rare finding of epidermal (infundibular) cysts of the ear that contained vellus hairs and with intervening severe solar elastosis (akin to Favre–Racouchot syndrome) has been proposed as a new dermatoheliosis.³²

Several histological variations in the epidermal lining have been reported. These include focal epidermal proliferation,³³ a seborrheic keratosis-like change,³⁴ basal hyperpigmentation and melanin incontinence (seen in black patients),^{35,36} melanophagic proliferation,³⁷ focal pilomatixoma-like changes (usually in kindreds with Gardner's syndrome),^{20,38,39} clear cell change,⁴⁰ cornoid lamellation,³³ epidermolytic hyperkeratosis,^{33,41} histological changes of Darier's disease,⁴² pyogenic granuloma formation,⁴³ Paget's disease,³³ basal cell carcinoma,³³ mycosis fungoides, and Bowen's disease.⁴⁴ Small papillary projections of follicular germinative cells emanating from the basal layer of the cyst wall are a rare occurrence.⁴⁵ Some of these projections may branch and form a reticulate pattern. The term ‘trichoblastic

Figure 16.1 Epidermal cyst. There is a thin lining of stratified squamous epithelium with a granular cell layer and loosely woven keratin contents. (H&E)

infundibular cyst has been suggested for this histological variant.⁴⁵ Melanoma *in situ* has been reported within the epithelial lining of a cyst, in contiguity with an adjacent malignant melanoma of epidermal origin.⁴⁶ More recently, a melanoma arising from an epidermal cyst has been reported in the absence of a contiguous melanoma of epidermal origin.⁴⁷ The only variations in cyst contents that occur are (1) the formation of spherules of keratin that are closely packed and uniform in dimensions⁴⁸ and (2) calcification, a common occurrence in cysts on the scrotum, where the cysts are sometimes multiple.⁴⁹ Specific histological features are usually seen in HPV-related cysts (see later). In a study of epidermal cysts of the sole, most showed foci of parakeratosis and focal lack of a granular layer, particularly in the upper portion of the cyst wall.⁵⁰ The cysts contained compact orthokeratotic material. The HPV status of these cysts was not obtained, but the histology of these cysts is remarkably similar to those described for HPV-related cysts (see later). Epidermal cysts express keratin 10 (K10), filaggrin,^{51,52} and some members of the S100 protein family.⁵³ Cases of malignant transformation,⁵⁴⁻⁵⁶ reported in the older literature, have been questioned because some, at least, represent proliferating trichilemmal cysts (see p. 513) or proliferating epidermal cysts (see later). Cases of unequivocal squamous cell carcinoma arising in epidermal cysts have been reported.⁵⁷ Despite the low risk of malignant transformation, it is generally agreed that all suspected cysts should be submitted for histological examination.⁵⁸

Differential diagnosis

Superficial shave biopsies showing changes suggestive of epidermal cysts may miss deeper foci that would point to a different diagnosis; examples include warty dyskeratoma, branchial cleft cyst, or pilomatricoma-like changes that are observed in the cysts associated with Gardner's syndrome. Milia-like formations can also be observed in the periphery of keratoacanthomas, and therefore a partial biopsy showing only the edge of such a lesion can be misinterpreted as an epidermal cyst. Trichilemmal cysts are usually easily distinguished by their distinctly palisaded basilar layer, swollen periluminal keratinocytes with sparse or absent keratohyalin granules, and homogeneous, eosinophilic keratin; however, hybrid cysts are sometimes seen that show areas with features of both epidermal and pilar cysts – features that support a follicular origin for a subset of these cysts (see later). Markedly inflamed lesions can resemble foreign body granulomas of other types or infection-induced granulomas. In those instances, careful search for cyst wall fragments or keratin flakes can point to the correct diagnosis.

HPV-RELATED EPIDERMAL CYSTS

Three distinctive, but rare, types of epidermal cyst have been reported in association with human papillomavirus infection. The first type, reported initially in Japan in 1986, usually involves pressure points on the plantar surface of the feet.^{59,60} Other sites are rarely involved.^{61,62} Lesions are usually solitary. HPV-60 has been demonstrated in most cases;⁶³ HPV-57 is rare.⁵⁹ Eccrine ductal structures are sometimes noted in the cyst wall, suggesting that HPV infection of eccrine ducts may have a pathogenetic role in some cases.^{63,64} However, immunostaining with monoclonal antibodies against various cytokeratins does not support this view.^{65,66} These conflicting findings may have been resolved.⁶⁷ It appears that these cysts express cytokeratin immunoreactivity identical to that of suprabasal layers of the epidermis resulting from epidermoid metaplasia of superficial eccrine ducts.⁶⁷ Epidermal implantation may also be involved in the pathogenesis.^{65,66}

In the second type (verrucous epidermal cysts), an HPV genome produces verrucous changes in the epithelial lining.⁶⁸⁻⁷⁰ One report demonstrated HPV-20 and HPV-34, which are epidermodysplasia verruciformis-associated strains.⁷¹ The cysts do not usually involve the palms or soles.^{72,73}

In the third type, a cystic structure mimicking molluscum bodies developed on the big toe.⁷⁴ It resulted from HPV-1 infection. Implantation of a fragment of HPV-infected epidermis was thought to be the mechanism involved in its formation.⁷⁴

The DNA of HPV-8 and that of HPV-6 have been demonstrated within biopsy specimens of three cysts from a patient with epidermodysplasia verruciformis.⁷⁵ The patient had many other cysts that were not tested for the presence of HPV.⁷⁵

Histopathology^{1,59,63,68}

Epidermal cysts associated with HPV-60 infection are well-demarcated cysts in the dermis continuous with the overlying epidermis at the top of the cyst. Scattered keratinocytes in the upper layers of the epithelial lining contain intracytoplasmic, eosinophilic inclusions.^{76,77} In addition, vacuolar structures are present in the keratinous (horny) material within the cyst. Parakeratotic nuclei are often present in this keratinous material. Ductal structures expressing carcinoembryonic antigen (CEA) may be found in the cyst walls.⁶⁴ In HPV-related cysts arising away from palmoplantar surfaces, no histopathological feature has been shown to be predictive for the presence of HPV-60.⁶²

In the HPV-related verrucous cysts, there is an epidermal cyst lined by a papillated and/or digitated epithelium with focal, prominent hypergranulosis and irregular keratohyaline granules (Fig. 16.2).⁶⁸ Squamous eddies, reminiscent of those seen in inverted follicular

Figure 16.2 (A) HPV-related epidermal cyst. (B) The lining has a papillated appearance. (H&E)

Figure 16.3 Proliferating epidermal cyst. There are multilocular, keratin-filled cystic spaces. (H&E)

keratosis, are often present in the epithelial lining. Vacuolated keratinocytes, resembling koilocytes, have been present in some cases.⁷⁰

PROLIFERATING EPIDERMAL CYST

In a series of 96 cases of proliferating epithelial cysts published in 1995, 63 were of trichilemmal type and 33 of epidermal type.⁷⁸ The trichilemmal variants had a predilection for females (71% of cases) and the scalp (78% of cases), whereas the proliferating epidermal cysts had a male preponderance (64%) and a more widespread distribution involving the pelvic and anogenital region as well as the scalp, upper extremities, and trunk.⁷⁸ Carcinomatous change developed in 20% of the proliferating epidermal cysts.

Histopathology

Proliferating epidermal cysts are subepidermal cystic tumors that often connect with the overlying epidermis by a narrow opening or through a dilated hair follicle.⁷⁸ An underlying epidermal cyst is often present, although this constitutes only a small part of the lesion. The lesion consists of multilocular cystic spaces containing keratinous material or proteinaceous fluid. The proliferating epithelium, which may show squamous eddies, extends into the adjacent stroma, but there is usually still some circumscription (Fig. 16.3). The squamous cells may have copious pale cytoplasm. Epidermal-type keratinization is a prerequisite for the diagnosis. The degree of cellularity and atypia is variable.⁷⁸ Carcinomatous change is characterized by infiltration into the surrounding dermis and subcutis, marked nuclear atypia, pleomorphism, and frequent mitoses.

TRICHILEMMAL (TRICHILEMMAL, SEBACEOUS, ISTHMUS-CATAGEN) CYST

Trichilemmal cysts are also known as isthmus-catagen cysts in some areas of the world, reflecting the similarity of the cyst lining to the isthmus portion of the follicle and the epithelium of the lower segment of a follicle in late catagen.⁷⁹ Clinicians have been slow to embrace this term, and it is likely to be decades, or longer, before it attains worldwide acceptance. Pilar cyst has also been used to describe this

Figure 16.4 Trichilemmal cyst (sebaceous cyst). It is lined by stratified squamous epithelium exhibiting trichilemmal keratinization. (H&E)

Figure 16.5 Trichilemmal cyst with 'rupture' and ingrowth of inflammatory cells and granulation tissue. (H&E)

cyst. They are found as solitary or multiple intradermal or subcutaneous lesions with a predilection for the scalp. They are mostly asymptomatic.⁸⁰ There is a female preponderance. There is no punctum, and the cysts easily shell out at removal. Familial cases, often with multiple cysts, occur, and some of these have an autosomal dominant inheritance.⁸¹

The term '**trichilemmal cyst nevus**' has been used for the occurrence of multiple cysts arranged in a band-like pattern associated with multiple filiform hyperkeratoses and comedo-like plugs.⁸² This may be yet another variant of organoid nevus (nevus sebaceus).⁸²

The cysts are smooth with a cream to white wall and similarly colored, semisolid, cheesy contents.

Histopathology^{1,83}

The cysts are lined by stratified squamous epithelium showing trichilemmal keratinization in which the individual cells increase in bulk and vertical diameter toward the lumen (Fig. 16.4). This usually occurs without the formation of keratohyaline granules and resembles that seen in the external root sheath in the region of the follicular isthmus.⁸⁴ There is an abrupt change into the eosinophilic-staining keratin within the lumen. Cholesterol clefts are common in this keratinous material, and approximately one-fourth will show focal calcification of the contents; ossification of a trichilemmal cyst has rarely been reported.^{85,86} Trichilemmal cysts express both keratin 10 (K10) and 17 (K17).⁵¹ Approximately 10% have focal inflammation, but this differs from that seen in epidermal cysts. In trichilemmal cysts, there is a break in the wall with entry into the cysts of inflammatory cells and fibroblasts with subsequent organization (Fig. 16.5). Irregular hyperplasia of the epithelial lining may be a consequence of this. Sebaceous and apocrine differentiation have been reported in the wall.⁸⁷ In one case, Merkel cell carcinoma *in situ* developed in the wall of a trichilemmal cyst.⁸⁸

A verrucous variant of trichilemmal cyst has been reported.⁸⁹ HPV common antigens were demonstrated in the nuclei of the lining cells in this case.⁸⁹

Sometimes, the outermost epithelial portion of the cyst wall separates from the remainder of the cyst.⁷⁹ Focal separation is more common than complete splitting (Fig. 16.6). The retained basal epithelium may mimic an apocrine hidrocystoma or even a vascular malformation.⁷⁹

Under polarized light, the perpendicularly oriented bundles of tonofibrils can be seen in the lining epithelial cells, a feature of trichilemmal keratinization.⁹⁰ This mirrors the electron microscopic findings

Figure 16.6 Trichilemmal cyst with splitting of the outer part of the wall. In some areas, only a thin layer of cells was present, mimicking a hidrocystoma. (H&E)

of an increase of filaments in the maturing cells that aggregate to form larger fibrillary bundles. Keratohyaline granules are not usually seen.

A recent example of trichilemmal cyst nevus from the right occipital scalp showed multiple small cysts that were not arranged in a band-like configuration, in a lesion that lacked filiform hyperkeratoses or comedo-like plugs.⁹¹

PROLIFERATING AND MALIGNANT TRICHILEMMAL CYST

Although usually solid or only partly cystic, proliferating and malignant trichilemmal cyst is considered here because a spectrum of cases is observed, ranging from a trichilemmal cyst with minimal epithelial proliferation to a lesion with gross epithelial hyperplasia that is only minimally cystic and that may simulate a squamous cell carcinoma.^{78,92} Ackerman and colleagues believe that a proliferating trichilemmal cyst (pillar tumor) is a variant of squamous cell carcinoma.

They use the term 'proliferating trichilemmal cystic squamous cell carcinoma' for such cases.^{93,94} This view has not yet received wide acceptance,⁹⁵ and, indeed, the cytokeratin profile of these tumors differs from that of control squamous cell carcinomas.⁹⁶ This entity was first described by Wilson Jones as a proliferating epidermoid cyst.⁹⁷ Subsequent reports have not always made a distinction between proliferating trichilemmal cyst and proliferating epidermal cyst (discussed previously).

The tumors are large, measuring 2–10 cm or more in diameter. They are sometimes exophytic and even ulcerated.⁹⁸ They are most commonly found on the scalp of middle-aged or elderly females.⁷⁸ The extremities are rarely involved.^{78,99} Recurrence after excision and malignant transformation are both uncommon,^{100–102} metastatic spread is very rare.^{101,103–107} They may develop in organoid nevi,^{108,109} but most arise *de novo* or in a pre-existing trichilemmal cyst.^{98,110} HPV-21 was present in one malignant tumor in a patient with epidermodysplasia verruciformis.¹¹¹

Complete surgical excision is the treatment of choice. Mohs surgery has also been used to treat this lesion.¹¹²

Histopathology

There is a lobular proliferation of squamous cells, often with some peripheral palisading and sometimes showing focal areas of vitreous membrane formation. There may be focal cystic areas or remnants of a more obvious trichilemmal cyst at one margin (Fig. 16.7). The lesions are usually well circumscribed. Nests of squamous cells may extend into the adjacent connective tissue, simulating squamous cell carcinoma, but the proliferation of nests is mostly inwards into the cyst (Fig. 16.8). This contrasts with the outward extension of nests seen in proliferating epidermal cysts.

There are typical areas of trichilemmal keratinization and, in some cases, focal epidermal keratinization as well. There may also be vacuolated cells, variable cellular atypia,¹¹³ focal necrosis, squamous eddies, individual cell keratinization, and scattered mitoses. Sebaceous and acrosyringial differentiation were noted in one case.¹¹⁴ A spindle cell component has also been described.^{115,116} Features favoring the diagnosis of proliferating trichilemmal cyst over squamous cell carcinoma include the presence of trichilemmal keratinization, cyst formation, calcification, and the absence of a premalignant epidermal lesion.¹¹⁷ Aneuploidy does not always assist in the assessment of malignancy because this feature can be present in proliferating trichilemmal cysts.^{118–120} The diagnosis of a malignant proliferating trichilemmal

tumor usually requires the identification in some areas of an underlying benign component.¹⁰⁰ It also requires the presence of extensive cellular atypia and invasion, sometimes focal, of adjacent structures (Fig. 16.9).^{101,121} Other criteria that have been suggested as markers of malignancy include non-scalp location and size greater than 5 cm.¹⁰⁷ Uncommonly, a spindle cell carcinoma forms the malignant component.¹²² In one case, the spindle cells were positive for vimentin but not for keratin, epithelial membrane antigen, or S100 protein.¹²³ Stromal desmoplasia may be present in areas of malignant transformation. There is loss of CD34 immunostaining in some malignant lesions,¹²⁰ but it is retained in others.⁹⁶

Electron microscopy has confirmed the presence of areas of trichilemmal keratinization.¹²⁴

ONYCHOLEMMAL CYST

Subungual onycholemmal cysts, also known as subungual epidermoid inclusions, are an uncommon lesion occurring in the dermis of the nail bed.¹²⁵ There may be associated onychodystrophy, clubbing, ridging, thickening, pigmentation, or no change in the nail plate.¹²⁵

Histopathology¹²⁵

There are free-lying cysts within the dermis of the nail bed, although they appear to form by elongation of the rete ridges with cyst formation and the subsequent pinching off of the connection to the nail bed epithelium. The cysts contain onycholemmal keratin and calcification. There is no granular layer.

MALIGNANT ONYCHOLEMMAL CYST

Two cases of malignant onycholemmal cysts have been reported. The terms used have been 'malignant proliferating onycholemmal cyst' and 'onycholemmal carcinoma'.^{126,127} They presented as a slowly growing tumor of the nail unit.¹²⁶ It was thought to have arisen from a pre-existing subungual keratinous cyst. The lesion penetrated the underlying phalangeal bone.

Figure 16.7 Proliferating trichilemmal cyst. An early lesion with evidence of a pre-existing cyst at one edge. (H&E)

Figure 16.8 Proliferating trichilemmal cyst. This is part of a large tumor in which nests of squamous epithelium extend into the adjacent dermis. (H&E)

Figure 16.9 Malignant trichilemmal cyst (malignant proliferating trichilemmal tumor). (A) There is stromal infiltration by tumor islands with foci of trichilemmal keratinization. (B) On higher magnification, significant nuclear pleomorphism and mitotic activity can be observed. (H&E)

Histopathology

The tumor is composed of small keratinous cysts with abrupt central keratinization and of solid nests and strands of atypical keratinocytes.¹²⁶

HYBRID CYST

A hybrid cyst is one in which the lining of the upper portion shows epidermoid keratinization similar to an epidermal cyst, whereas the lower portion shows trichilemmal keratinization similar to that seen in a trichilemmal cyst.¹²⁸ There is a sharp transition between the two types of lining. A hybrid cyst should not be confused with a trichilemmal cyst showing very focal formation of a granular layer, which may be found in 10% of cases.¹²⁹

The term 'hybrid cyst' has been expanded to include any follicular cyst with two different types of epithelial lining.¹³⁰ In addition to those just described with epidermal (infundibular) and trichilemmal

differentiation, cysts may be found with epidermal and pilomatrical features (particularly in Gardner's syndrome), trichilemmal and pilomatrical differentiation,¹³¹ pilomatrical and steatocystoma features,¹³² epidermal and apocrine changes,^{133,134} isthmic-catagen (trichilemmal), pilomatrical, and syringocystadenoma papilliferum features,¹³⁵ and also eruptive vellus hair cyst features with steatocystoma, epidermal, or trichilemmal change.^{130,136} A hybrid follicular cyst with some features of those seen in Gardner's syndrome has now been seen in a patient with myotonic dystrophy.¹³⁷ A vellus hair cyst combined with an epidermal cyst and a benign melanocytic nevus has been reported.¹³⁸ A recent hybrid cyst was found to have infundibular, trichilemmal, and pilomatrical differentiation.¹³⁹

In a series of 15 cases of hybrid cysts reported from Japan, nearly half the cases occurred on the scalp and face. The most frequent histological type (60%) was the combination of epidermal (infundibular) and trichilemmal cysts.¹⁴⁰ A hybrid cyst of the parietal scalp has been associated with perforation of the skull, presumably from long-term pressure on the bone.¹⁴¹

HAIR MATRIX CYST

The hair matrix variant of epidermal cyst is seen more often in children and young adults. There is some resemblance to the pattern of differentiation seen in pilomatrixomas.

Histopathology

The cyst wall is composed of several layers of basaloid cells that mature to squamoid cells near the lumen (Fig. 16.10). This pattern recapitulates that seen in the normal hair matrix and cortex. Small cystic spaces are often present within the cyst wall. The lumen contains amorphous, keratinous material. If rupture occurs, a florid granulomatous reaction develops in the surrounding dermis.

CYSTIC PANFOLLICULOMA

Panfolliculoma is an exceedingly rare follicular neoplasm with differentiation toward both upper and lower segments of the hair follicle (see p. 919).¹⁴² There is infundibular, isthmic, matrical, and papillae-like differentiation. There are some overlap features between a trichoblastoma and matricoma. Some lesions present clinically as cysts. Grossly, they may be cysts measuring 3 or 4 cm in diameter.

Histopathology¹⁴²

The cystic variant has a thin wall approximately 0.1 cm in thickness. It is lined by infundibular epithelium having a granular layer. Solid aggregates of dark follicular germinative cells are present. Bulbs and papillae form in these areas. Matrical differentiation and shadow cells, as well as trichohyalin granules, are seen. Cytokeratin 903 and CK5/6 stain the tumor cells, whereas Ber-EP4 labels the germinative cells but not the follicular papillae.

PIGMENTED FOLLICULAR CYST

A rare, clinically pigmented cyst was first described in 1982.^{143–146} There are reports of a patient with multiple pigmented cysts.^{147,148} This entity should be distinguished from a pigmented epidermal cyst, in which melanin pigment is present in the wall of an epidermal cyst or in melanophages in the surrounding stroma.³⁶

Histopathology

The cyst is located in the dermis and has a narrow, pore-like opening to the surface. It contains laminated keratin as well as multiple,

Figure 16.10 (A) Hair matrix (matrical) cyst. (B) Matrical differentiation is present in the cyst wall. (H&E) (C) There is strong staining for β -catenin. (Immunoperoxidase stain for β -catenin)

Figure 16.11 (A) Pigmented follicular cyst. (B) The lumen of the cyst contains a number of pigmented hair shafts. (H&E)

pigmented hair shafts (**Fig. 16.11**). Degenerating hair shafts may be present.¹⁴⁹ The cyst is lined by stratified squamous epithelium showing epidermal keratinization, but in addition the lining may show rete ridges and dermal papillae – features not seen in epidermal cysts. Both epidermal and trichilemmal keratinization were present in the cysts removed from one of the patients with multiple lesions.¹⁴⁷

Closely related is the occurrence of a small follicular cyst containing pigmented hair shafts arising in a melanocytic nevus.¹⁵⁰

CUTANEOUS KERATOCYST

Cutaneous cysts are a feature of the nevoid basal cell carcinoma syndrome (see p. 814). Usually, these cysts are of epidermal type, but there are rare reports of patients with this syndrome in whom the cutaneous cysts resembled keratocysts of the jaw.^{151,152} They contained a thick brown fluid. There are reports of a cutaneous keratocyst arising independently of the nevoid basal cell carcinoma syndrome.^{153,154} It has been suggested that 'isthmic-anagen cyst' would be a more appropriate designation.¹⁵⁵

Histopathology¹⁵¹

The cysts have a corrugated or festooned configuration with a lining of several layers of squamous epithelium but with no granular layer.

Figure 16.12 Sebaceous duct cyst (keratocyst). There is a lining that resembles the sebaceous duct. (H&E)

Lanugo hairs were present in one cyst. There is a superficial resemblance to steatocystoma multiplex (see later), but there are no sebaceous lobules in the wall.

The author uses the term **sebaceous duct cyst** for cysts with a corrugated lining but no sebaceous lobules of steatocystoma on routine sectioning (Fig. 16.12). They are not as rare as the paucity of reports would suggest. There is a possibility that rare sebaceous lobules would be found on complete sectioning of the cyst. Keratocyst is an acceptable alternative term, but this term is usually associated with the cysts of the nevoid basal cell carcinoma syndrome.

VELLUS HAIR CYST

Eruptive vellus hair cysts, first reported in 1977,¹⁵⁶ occur as multiple, small (1–4 mm), asymptomatic papules with a predilection for the chest and axillae of children or young adults.^{157,158} The number of cysts varies from 20 to 200.¹⁵⁹ They are also found on the face,^{160–162} neck, and extremities. Unilateral involvement of the face has been reported.¹⁶³ They may have an autosomal dominant inheritance or occur sporadically.^{164,165} Ectodermal dysplasia and oculocerebrorenal syndrome (Lowe's syndrome; OMIM 309000) are rare associations.^{166–168} Spontaneous regression of the cysts has been reported, probably following the transepidermal elimination of the cyst contents.¹⁶⁹

Trichostasis spinulosa may rarely coexist with eruptive vellus hair cysts.¹⁷⁰

An extraction technique, similar to that proposed for steatocystoma multiplex (see below), has been proposed.¹⁷¹ Lasers have also been used in the management.¹⁷²

Histopathology¹⁵⁶

These small dermal cysts are lined by stratified squamous epithelium that may show focal trichilemmal as well as epidermoid keratinization. The lumen contains keratin and numerous transversely and obliquely sectioned vellus hair shafts (Fig. 16.13). These shafts are doubly refractile with polarized light. A rudimentary hair follicle may be attached to the wall. Hybrid cysts with features of both vellus hair cysts and steatocystoma are sometimes seen.^{130,173} There may be focal rupture of the cyst wall with a foreign body granulomatous reaction and associated dermal fibrosis and mild chronic inflammation.

Figure 16.13 Vellus hair cyst. The lumen of the cyst contains multiple small vellus hairs. (H&E)

Some cysts may show a connecting pore at the skin surface, the likely mechanism of the spontaneous regression mentioned previously.

If the cyst contents are expelled through a small incision and then placed in potassium hydroxide, the vellus hairs can be identified in a typical serpentine array.¹⁵⁹

Differential diagnosis

Eruptive vellus hair cysts have been reported in patients with steatocystoma, suggesting that these two entities are in some way related;^{173–176} both may be derived from the sebaceous duct.¹⁷⁷ However, their pattern of keratin expression is different: vellus hair cysts express K17, whereas steatocystomas express both K17 and K10.⁵¹ Milia can also occur in association with these two entities.¹⁷⁸ Occasionally, eruptive vellus hair cysts can be confused with lesions of molluscum contagiosum or acne vulgaris.

Dermoscopy can be helpful in this distinction: The vellus cyst presents as a rounded structure with central yellow-white plaque and erythematous halo, whereas molluscum lesions show a polylobular white-yellow body with a peripheral crown of hairpin vessels, and inflammatory acne lesions show rounded, white centers with thin brown borders and peripheral erythema.¹⁷⁹

STEATOCYSTOMA MULTIPLEX

Steatocystoma multiplex is characterized by multiple yellowish to skin-colored papules or cysts measuring from less than 3 mm in diameter to 3 cm or more. They may be found on the face,^{180–185} scalp,^{186–188} trunk, vulva,¹⁸⁹ axillae, and the extremities,¹⁹⁰ but they have a predilection for the chest. Rarely, they have a linear distribution.¹⁹¹ They are mostly sporadic, but familial cases with autosomal dominant inheritance are well documented. Other abnormalities may be present in the inherited cases.¹⁸¹ The occurrence of steatocystoma multiplex in Alagille syndrome may be fortuitous¹⁹² but not their occurrence in association with trichoblastomas and trichoepitheliomas.¹⁹³ Patients with only a solitary lesion (steatocystoma simplex) are seen rarely.^{189,194} The cysts usually present in adolescents as asymptomatic lesions, but infected cysts (steatocystoma multiplex suppurativum) may be painful.^{195,196} Steatocystoma is thought to represent a nevoid malformation of the pilosebaceous duct. Mutations in K17, similar to those found in pachyonychia congenita, have been found in some patients with steatocystoma multiplex.^{197–201}

A modified surgical technique involving puncture of the cyst, evacuation of cyst contents, and extraction of the sacs through a small incision has been proposed as the method of choice for their removal.²⁰²

Histopathology

The lining of the dermal cysts is usually undulating due to collapse of the cyst. It is composed of stratified squamous epithelium, only a few cells thick and without a granular layer. The characteristic feature is the presence of sebaceous glands of varying size in or adjacent to the wall (Fig. 16.14). A ribbon-like cord of epithelial cells connects the cyst with the epidermis, but this may not be seen in the plane of section. One pilar unit is associated with each cyst, and the cyst may contain one or more lanugo hairs. Large polygonal cells with abundant granular cytoplasm form part of the lining of the cyst on rare occasions. Such cells have the immunohistochemical characteristics of the macrophage/monocyte lineage.¹⁸⁸ Spherules ('myospherulosis'), formed by masses of erythrocytes in the presence of oil-containing substances, have been reported in the lumen.²⁰³ Smooth muscle has been noted in the wall.²⁰⁴

Figure 16.14 (A) *Steatocystoma multiplex*. (B) Sebaceous glands are present within the cyst wall. (H&E)

Hybrid cysts with features of both steatocystoma and vellus hair cysts are sometimes seen;^{130,173,205,206} epidermal cysts may form a third component.¹³⁶ Cysts without sebaceous lobules in the wall resemble keratocysts. The author uses the term **sebaceous duct cyst** for these solitary lesions (discussed previously). The presence of a sebaceous adenoma in the wall of a steatocystoma has been called a '**steatosebocystadenoma**'.²⁰⁷

Electron microscopy

The keratinization takes place without the formation of keratohyaline granules, a feature that is characteristic of the sebaceous duct.¹⁸⁰

MILIUM

A milium is a small (1 or 2 mm in diameter) dermal cyst that may arise from the pilosebaceous apparatus or eccrine sweat ducts.²⁰⁸ Milia may be seen in the newborn as congenital lesions, or they may develop later in life secondary to dermabrasion; to contact dermatitis;²⁰⁹ to the topical application of corticosteroids;²⁰⁸ to radiotherapy; and as a consequence of subepidermal blistering disorders such as porphyria cutanea tarda, epidermolysis bullosa dystrophica, polymorphic light eruption,²¹⁰ and second-degree burns. They have also been reported in association with discoid lupus erythematosus,²¹¹ pseudoxanthoma elasticum,²¹² healed leishmaniasis,^{213,214} regressing plaques of mycosis fungoides,²¹⁵ a congenital hemangioma,²¹⁶ and some inherited disorders.²¹⁷ One such syndrome is the Bazex–Dupré–Christol syndrome (follicular atrophoderma and basal cell carcinoma; OMIM 301845), which maps to Xq24–q27. The *UBE2A* gene has been proposed as a candidate gene,²¹⁸ but the search for the gene is still ongoing.²¹⁹ Another is the oral–facial–digital syndrome type 1 (OMIM 311200), an X-linked dominant disorder. The gene, *OFD1*, maps to Xp22.3–p22.2.²²⁰ A third is the Loews–Dietz syndrome type 1A (OMIM 609192), an autosomal dominant disorder that features the early development of aortic aneurysms and dissections, craniosynostosis, hypertelorism, cleft lip and palate, bifid uvula, bluish sclera, arachnodactyly, pectus deformities, and velvety, translucent skin. The involved gene is the transforming growth factor- β receptor gene *TGFBRI*, located at 9q22.33.²²¹

Milia most commonly occur as multiple lesions on the cheeks and forehead, but they may involve the genitalia or other sites, depending on the predisposing lesion.^{222,223} A rare eruptive form^{224,225} and an erythematous plaque variant (milia en plaque) have been reported.^{217,226–236} Milia en plaque usually occurs in a periauricular distribution;²³⁷ bilateral lesions have been described in retroauricular areas²³⁸ and eyelids.²³⁹ It has arisen in association with lupus erythematosus²⁴⁰ and in a renal transplant patient.²⁴¹ There have been several case reports describing an association between multiple milia and multiple myeloma-associated AL amyloidosis with cutaneous involvement.²⁴²

Treatment options for milia en plaque are limited, although spontaneous regression occurs occasionally.²³⁶ Simple extraction or topical tretinoin are the most frequently tried options.²³⁶ Oral etretinate has also been used successfully to treat milia en plaque.²⁴³ Retinoids suppress the expression of involucrin and cytokeratins 6 and 16. Topical tretinoin has been used to treat eruptive milia.²⁴⁴

Histopathology

The small cysts are lined by several layers of stratified squamous epithelium with central keratinous material, resembling a small epidermal cyst. They may be connected to a vellus hair follicle or eccrine sweat duct, usually the latter.²⁴⁵ Milia differ from comedones, which are keratinous plugs in dilated pilosebaceous orifices. Closed comedones, which may be particularly prominent in the condition known as nodular elastoidosis with cysts and comedones (Favre–Racouchot disease),^{246,247} may superficially resemble milia. However, comedones are more likely to contain old hair shafts and laminated keratinous

material containing numerous bacteria.²⁴⁸ The term **comedonal cyst** has been used for comedones with cystic dilatation (see later). Some ruptured milia produce an unusually florid granulomatous reaction of foreign body type that has a distinctive appearance, even though the milium has been destroyed.

COMEDO/COMEDONAL CYST

A comedo is an impaction of horny cells in the lumen of a sebaceous follicle. They may be open ('blackhead') with a wide patulous orifice or closed ('whitehead') with a small orifice, not always seen in a random hematoxylin and eosin (H&E) section. They were discussed previously as a component of acne vulgaris (see p. 460). Comedones are common in chloracne (see p. 462) and in the Favre–Racouchot syndrome (see p. 394), a rare variant of which appears to have been described on the ears.³² Flexural comedones have been described recently in children. They were most common in the axillae (88%), but they were also found in the groin and antecubital fossa.²⁴⁹ Most cases were unilateral. The term **childhood flexural comedones** was applied to the 40 reported cases; the number of cases in the report suggests that this entity is not uncommon.²⁴⁹ The term **idiopathic disseminated comedones** refers to the occurrence of multiple comedones in a widespread distribution. Only one case appears to have been reported.²⁵⁰

Comedones may be familial.²⁵¹ A familial form with dyskeratosis in the wall of the cysts has been called familial dyskeratotic comedones (see p. 787).

Comedones are follicular retention cysts. Although usually small, some deserve the appellation *comedonal cyst*.

Histopathology

A comedo is a cystically dilated hair follicle containing abundant keratinous material. As discussed previously, they may have a patulous orifice (open comedones) or a narrow orifice, not always seen in plane of section (closed comedones). Severe solar elastosis accompanies those seen in the Favre–Racouchot syndrome. No criteria have been proposed for the designation 'comedonal cyst' as opposed to 'comedo'.

ECCRINE HIDROCYSTOMA

Eccrine hidrocystomas are usually solitary lesions of the face, trunk, or popliteal fossa, with a strong predilection for the periorbital area.^{252,253} Cases with multiple (up to 200 or more) lesions are well documented.^{254–257} There is a slight preponderance of adult females. Clinically, the lesions are usually translucent, pale blue, dome-shaped, cystic papules. The development of a squamous cell carcinoma in an eccrine hidrocystoma is a very rare complication.²⁵⁸

The existence of this entity has been challenged; many, if not all, of these lesions are now regarded as being of apocrine type, but cases continue to be reported.²⁵⁹

Histopathology

The cysts are unilocular and situated in the dermis, often in close proximity to eccrine glands (Fig. 16.15). The wall is composed of two layers of cuboidal epithelium with eosinophilic cytoplasm (Fig. 16.16). Sometimes the lumen contains small amounts of pale eosinophilic secretions. There is no evidence of decapitation secretion, but this may simply be a consequence of marked flattening of the lining cells by the intraluminal contents.

Electron microscopy

There are two cell layers with a peripheral basement membrane and extensive microvilli along the luminal border.²⁶⁰ These findings are similar to those of the eccrine duct.

Figure 16.15 Eccrine hidrocystoma. In this case, the thin-walled cyst, lined by two layers of cuboidal epithelium, is in close proximity to the eccrine glands. (H&E)

Figure 16.16 Eccrine hidrocystoma. It has been suggested that many such lesions are really of apocrine type. Attenuation of the lining may be responsible for loss of the 'decapitation' secretion in some cases; on the other hand, both apocrine and eccrine ducts are lined by two layers of cuboidal cells. (H&E)

APOCRINE HIDROCYSTOMA

Apocrine hidrocystoma (apocrine gland cyst, apocrine cystadenoma) is regarded by some as an adenomatous cystic proliferation of apocrine glands and by others as a simple retention cyst.²⁶¹ Apocrine hidrocystomas are almost invariably solitary lesions, a few millimeters in diameter, on the head or neck of middle-aged to older adults.²⁶² A large variant has been described,²⁶³ and patients with multiple lesions have been observed.^{264–267} Multiple cysts may be a marker of two rare inherited disorders – the Schöpf–Schulz–Passarge syndrome and a form of focal dermal hypoplasia.²⁶⁶ Clinically, the lesions resemble eccrine hidrocystomas with a translucent or bluish hue.²⁶⁸ Their contents are colorless or brown to black. Interestingly, they do not occur in the usual sites in which apocrine glands are found.²⁶⁹ Examples of this include the tip of the finger²⁷⁰ and the extremities.²⁷¹ They may arise in an organoid nevus.²⁶¹ Cysts may also develop from the duct and secretory segment of Moll's gland, a modified apocrine gland of the eyelid.^{266,272,273}

Figure 16.17 Apocrine hidrocystoma. The cuboidal lining of the cystic cavity is indistinguishable from that of eccrine hidrocystoma. (H&E)

Figure 16.18 Apocrine cystadenoma. This lesion is lined by cells that display decapitation secretion. Papillary projections within the cyst lumina are apparent. (H&E)

Histopathology

Some cysts are lined by two layers of cuboidal epithelial cells, in which case (other than proximity to eccrine sweat glands) they may be indistinguishable from eccrine hidrocystomas (Fig. 16.17).^{274,275} It is now thought that most eccrine hidrocystomas are probably of apocrine origin. Other cysts are unilocular or multilocular with a lining of columnar epithelium with basal nuclei and an underlying flattened layer of elongated, basal myoepithelial cells. Characteristically, there is ‘pinching off’ (‘decapitation’) of the cytoplasm of the luminal border of the lining cells, typical of apocrine secretory activity. In nearly half the cases, there are local areas of hyperplastic epithelium with microcysts in the lining and intracystic papillary projections with a core of vascularized connective tissue. Sugiyama *et al.* recommend that a lesion with true papillary features be designated apocrine cystadenoma rather than apocrine hidrocystoma (Fig. 16.18).²⁷⁶ The presence of keratinizing squamous epithelium adjacent to apocrine epithelium occurs in one variant of hybrid cyst (see p. 515).

The secretory cells may contain PAS-positive diastase-resistant granules. Carcinoembryonic antigen (CEA) may also be present in both apocrine and eccrine cystadenomas. Occasionally, rounded, lamellar, acellular concretions called *Liesegang rings* can be seen in the lumen of these cysts (we have also seen them in eccrine hidrocystoma); they can at first resemble parasitic organisms, but in reality they represent an *in vivo* chemical precipitation phenomenon, in which there is supersaturation of a colloidal solution or gel with heavy ions that undergo intermittent chelation.²⁷⁷

Electron microscopy

The basal myoepithelial cells and the secretory cells show abundant secretory granules, decapitation secretion, and usually annulate lamellae.²⁷⁸

DEVELOPMENTAL CYSTS

Included in this group are cysts derived from embryological vestiges such as the branchial cleft, thyroglossal duct, tracheobronchial bud,

urogenital sinus, and müllerian structures.²⁷⁹ Others arise along lines of embryological closure. The term ‘cutaneous ciliated cyst’ has been applied to those that have in common a ciliated columnar epithelial lining but that have been given different names according to their topographical localization.²⁸⁰ Included in this concept are bronchogenic cysts, cutaneous ciliated cyst of the lower limbs, branchial and thyroglossal cysts, and cutaneous endosalpingiosis.²⁸¹ The term is best restricted to the cutaneous ciliated cyst of the lower limbs (see p. 522).

Cystic lesions devoid of an epithelial lining may occur in association with heterotopic brain tissue (see p. 1059).²⁸²

BRONCHOGENIC CYST

A bronchogenic cyst is present at or soon after birth, most often in the midline near the manubrium sterni.^{280,283–286} It has been reported on the chin,^{287,288} the neck, and even the shoulder and scapular region,^{289,290} these latter examples are presumed to be derived from sequestered cells of the tracheobronchial bud, although an equally valid argument can be made for a branchial origin for many of these cysts.^{291,292} They present as a cyst or as a draining sinus. Bronchogenic cysts are four times more common in males than in females.²⁹³

The cysts are unilocular and situated in the dermis or subcutaneous tissues. They contain cloudy fluid.

Histopathology

The cysts are lined by ciliated and mucin-producing pseudostratified columnar or cuboidal epithelium (Fig. 16.19). Stratified squamous epithelium may be present in the outer part of the cyst in those presenting as a sinus on the skin surface.²⁹⁴ Gastric mucosa of antral type has been reported in one bronchogenic cyst.²⁹⁵ Smooth muscle and even mucous glands are found commonly in the wall, but cartilage is present only occasionally. There may be some inflammation and fibrosis adjacent to the cyst; lymphoid follicles, common in the wall of branchial cleft cysts (see later), are rare in bronchogenic cysts, but they have been described.^{296–299} **Ectopic respiratory mucosa**, without an associated cyst, is a rare finding in the skin.^{300,301}

Figure 16.19 (A) Bronchogenic cyst with a collection of mucous glands in the wall. **(B)** The lining is pseudostratified columnar with occasional goblet cells. There are smooth muscle bundles in the wall. (H&E)

Figure 16.20 Branchial cleft cyst. This particular cyst is lined by stratified squamous epithelium. It is surrounded by a heavy lymphoid infiltrate. (H&E)

BRANCHIAL CLEFT CYST

Branchial cleft remnants present clinically as cysts, sinus tracts, skin tags, or combinations of these lesions.^{292,302,303} Those derived from the second branchial pouch are usually found along the anterior border of the sternomastoid muscle of children or young adults, whereas those of first pouch origin arise near the angle of the mandible or postauricular region.³⁰⁴ They may be found at any depth between the skin and pharynx. Secondary infection may cause sudden swelling of the lesions.

The cysts contain turbid fluid, rich in cholesterol crystals. Squamous cell carcinoma is a rare complication in lesions of long standing.^{305,306} Papillary thyroid carcinoma arising from ectopic thyroid tissue within a branchial cleft cyst would seem to be a rare phenomenon, but a spate of case reports have appeared within the past several years.^{307–311}

Histopathology

The cysts are lined mostly by stratified squamous epithelium, but deeper parts may have a lining of ciliated columnar epithelium. A heavy lymphoid infiltrate invests the cyst or sinus wall, and this includes lymphoid follicles (Fig. 16.20). Mucinous glands and cartilage are occasionally present in the wall;²⁹¹ thymic tissue has also been reported.³¹²

Branchial cleft anomalies differ from bronchogenic cysts by their location, the common occurrence of lymphoid follicles and stratified squamous epithelium, and the rarity of smooth muscle.²⁹⁷

Figure 16.21 Thyroglossal duct cyst. This cyst was lined in part by ciliated epithelium. Thyroid follicles can be seen in the left side of the image. (H&E)

Figure 16.22 Thymic cyst. The cyst is lined by pseudostratified columnar epithelium in which cilia could be identified. The wall contains lymphoid tissue; a Hassall corpuscle can be seen (arrow). (H&E)

THYROGLOSSAL CYST

Most examples of thyroglossal cyst are deep lesions in the midline of the neck and therefore beyond the scope of this volume.^{181,313} There is one report of a depressed lesion in the midline of the neck, present since birth, which consisted of tubular glands lined by respiratory epithelium, opening onto the skin surface.²⁹¹ Deeper branching tubules penetrated into the underlying striated muscle. The lesion was presumed to be of thyroglossal duct origin. A cyst reported in the lateral neck, attached to the thyroid gland, was most likely a foregut remnant. It resembled, in part, a bronchogenic cyst, but the wall also contained pancreatic tissue.³¹⁴

Histopathology

Thyroglossal duct cysts may be associated with thyroid follicles. They lack smooth muscle or cartilage in their walls. The lining epithelium may be ciliated (**Fig. 16.21**).

THYMIC CYST

Thymic cysts are rare cysts found in the mediastinum or neck. The cervical lesions usually present as painless swellings in children or adolescents.³¹⁵⁻³¹⁷ Thymic cysts are thought to arise from remnants of the thymopharyngeal duct, a derivative of the third pouch. They are most often found posterior to a lateral lobe of the thyroid, more often on the left-hand side.

The cysts are unilocular or multilocular and measure from 1 to 15 cm in diameter. The contents are variable, ranging from yellow-brown fluid to cloudy or gelatinous material. Cholesterol crystals may be present.

Rarely, carcinomas may arise in thymic cysts.³¹⁸

Histopathology

Thymic cysts are lined by one or more of the following epithelia: squamous, columnar, cuboidal, or pseudostratified columnar. The cyst lining may be ciliated.³¹⁹ Occasionally, the cyst is devoid of an epithelial lining and has a fibrous tissue lining only. The wall characteristi-

cally contains Hassall's corpuscles, and in addition there may be lymphoid tissue, cholesterol granulomas, and sometimes parathyroid tissue (**Fig. 16.22**).³¹⁵

Thymic remnants, without cyst formation, have been reported in the skin of the neck.³²⁰

CUTANEOUS CILIATED CYST OF THE LOWER LIMBS

The term 'cutaneous ciliated cyst' is sometimes applied to several varieties of developmental cysts that, although lined by ciliated epithelium, are of quite different origin (discussed previously). It is mostly restricted to a rare cyst that arises on the lower extremities of women in the second and third decade.³²¹⁻³²⁴ Rarely, it may occur at other sites, such as the abdominal wall and umbilicus.³²⁵⁻³²⁷ Recent cases have occurred on the knee,³²⁸ finger,³²⁹ and gluteal cleft.³³⁰ The cysts are less than 3 cm in diameter. They have been thought to be of müllerian origin, but the occurrence of rare cases in males has raised the possibility of an origin from an eccrine sweat gland.³³¹⁻³³⁴ Ciliated cysts in the perineal region of males are thought to be derived from embryonic remnants of the cloacal membrane.^{335,336} A perineal lesion has also been reported in a female.³³⁷

In a case of cutaneous ciliated cyst removed from the scalp, estrogen and progesterone receptors were demonstrated in the nuclei of the lining cells.³³⁸

Histopathology

The cyst is lined by ciliated cuboidal to columnar epithelium with pseudostratified areas (**Fig. 16.23**). Focal squamous metaplasia is sometimes present; mucinous cells are rare.³³⁹ The cysts may be multilocular, and there are often papillary projections into the lumen. Glandular and smooth muscle elements are absent.³⁴⁰ Strong dynein positivity has been observed in the apical portion of the lining cells with immunohistochemistry.³³⁷ This pattern is similar to normal salpingeal epithelium – support for a müllerian origin.

The epithelial lining cells express progesterone receptor and epithelial membrane antigen but not carcinoembryonic antigen.³²⁵

Figure 16.23 Cutaneous ciliated cyst. The cyst is partly collapsed with some infolding of the wall. The lining is ciliated. (H&E)

Figure 16.24 Vulval mucinous and ciliated cyst. The lining is composed of cuboidal to pseudostratified columnar epithelium. Cilia are present in this example. (H&E)

VULVAL MUCINOUS AND CILIATED CYSTS

Vulval mucinous and ciliated cysts are found in the vestibule of the vulva.^{341,342} They vary in size from 0.5 to 3.0 cm or more. Included among the cases reported have been several instances of Bartholin's cyst. Vulval mucinous and ciliated cysts are presumed to be of urogenital sinus origin.

Histopathology

The cysts are lined by pseudostratified ciliated columnar epithelium and/or mucinous epithelium (Fig. 16.24). There may be areas of squamous metaplasia.

MEDIAN RAPHE CYST

'Median raphe cyst' is the preferred term for midline developmental cysts found at any point from the external urethral meatus to the anus,

including the ventral aspect of the penis, the scrotal raphe, and the perineal raphe, but most commonly near the glans penis.³⁴³⁻³⁴⁶ They are usually solitary, but multiple small papules in a linear arrangement may occur.³⁴⁷ They are thought to arise as a result of defective embryological closure of the median raphe, but some may result from the anomalous outgrowth of the entodermal urethral lining (urethroid cyst).^{348,349} They are most commonly diagnosed in the first three decades of life. Abrupt onset of a median raphe cyst may be precipitated by local trauma or secondary infection.³⁵⁰ Canals coursing longitudinally in the line of the median raphe are sometimes found.³⁵¹

Most raphe cysts are less than 1 cm in diameter. The contents are usually clear, but they may be turbid if there are abundant mucous glands in the wall.

Histopathology³¹²

Median raphe cysts are situated in the dermis, but they do not connect with the overlying surface epithelium. They are lined by pseudostratified columnar epithelium, which may be quite attenuated in some areas. Occasionally, mucous glands are present in the wall, but ciliated cells are rare.^{352,353} Pigmented cysts, resulting from the presence of melanocytes, have been reported.³⁵⁴ A recent example of pigmented median raphe cyst was lined by several layers of cuboidal cells and demonstrated basilar melanin within epithelial cells and Melan-A positive melanocytes; stains for apocrine gland with gross cystic disease fluid protein and for myoepithelial cells with smooth muscle actin were negative.³⁵⁵ In cysts situated near the meatus, the lining is usually of stratified squamous epithelium (Fig. 16.25).

Immunohistochemistry of two cases showed strong staining of the epithelial lining cells with CK7 and CK13 but not CK20.³⁵⁶

DERMOID CYST

Dermoid cysts are rare subcutaneous cysts of ectodermal origin found along lines of embryonic fusion, particularly at the lateral angle of the eye or the midline of the forehead or neck.³⁵⁷ Involvement of the scalp, mouth, and penis is rare.³⁵⁸⁻³⁶⁰ Dermoid cysts arising in the midline of the dorsum of the nose frequently have an overlying fistula communicating with the skin surface and the underlying cyst, which is sometimes quite deep.³⁶¹⁻³⁶⁴ The terms **fistula of the dorsum of the nose** and **nasal dermoid sinus cyst** are used for this superficial component.^{362,365} A tuft of hair usually protrudes from the central pit. If numerous sebaceous glands are present, the lesion may present as a yellowish plaque.³⁶⁶ A similar dermal 'sinus' has been reported in the occipital region of the scalp, overlying an intracranial dermoid cyst.³⁶⁷ The term **congenital dermoid fistula of the anterior chest region** has been used for yet another variant of this same process.³⁶⁸

Dermoid cysts are usually asymptomatic masses present at birth, but inflammation, often secondary to trauma, may draw attention to a pre-existing lesion in an older person.

The cysts are unilocular structures between 1 and 4 cm in diameter, containing fine hair shafts admixed with variable amounts of thick yellowish sebum.

The case reported as multiple dermoid cysts on the cheek had some unusual features, although the authors stressed that their case was different from steatocystoma.³⁶⁹

The subcutaneous cyst reported as a **cystic teratoma** has features of both a dermoid and a bronchogenic cyst (see later).³⁷⁰ The sacrococcygeal teratoma reported by Dhingra *et al.* may have been a conjoint parasitic twin.³⁷¹

Histopathology³⁵⁷

Dermoid cysts are lined by keratinizing squamous epithelium with attached pilosebaceous structures (Fig. 16.26). Nonkeratinizing squamous epithelium with admixed goblet cells resembling conjunctival

Figure 16.25 (A) Median raphe cyst. (B) Islands of squamous epithelium are interspersed between mucin-secreting epithelium. (H&E)

epithelium has been reported in orbital dermoid cysts.³⁷² Another rare finding is the presence of basaloid proliferations of the cyst wall, possibly representing primordial hair follicles.³⁷³ Sebaceous glands may empty directly into the cyst, the lumen of which contains hair shafts and keratinous debris. Eccrine and apocrine glands, as well as smooth muscle, may be present in the wall of up to one-fourth of the cases. Partial rupture of the cyst, resulting in a local foreign body granulomatous reaction, may be found. Focal calcification is a rare finding.

The fistulous tract sometimes found in association with midline dermoids of the nose is lined by the same elements as are found in the cyst wall.³⁶² The **dermoid fistula of the anterior chest** (discussed previously) was a thin sinus tract lined by stratified squamous epithelium with hair follicles and sebaceous glands arising from the lining.³⁶⁸

CYSTIC TERATOMA

Several cases of cystic teratoma of the skin have been reported in the English language literature.^{370,374,375} The lesions were present at

birth. They have involved the glabellar region,³⁷⁴ the back,³⁷⁰ and the knee.³⁷⁵

Histopathology

A diversity of tissue types may be present. One of the reported cases was composed of respiratory epithelium, thyroid, and nervous tissue as well as striated and smooth muscle.³⁷⁴ Another case was lined by gastrointestinal mucosa,³⁷⁵ whereas another resembled a dermoid cyst with the addition of areas lined by pseudostratified, ciliated epithelium with goblet cells and occasional seromucinous glands and some surrounding smooth muscle.³⁷⁰

OMPHALOMESENTERIC DUCT CYST

Omphalomesenteric duct cysts arise in the periumbilical area.³⁷⁶ They may be associated with a Meckel's diverticulum.

Histopathology

The cysts may be connected to the skin surface, with gastrointestinal mucosa adjoining the stratified squamous epithelium of the adjacent

Figure 16.26 (A) Dermoid cyst. (B) A pilosebaceous structure is attached to the cyst wall. (H&E)

skin (**Fig. 16.27**). The mucosa may be of gastric, colonic, or small bowel type. Smooth muscle may be present in the wall.

MISCELLANEOUS CYSTS

PARASITIC CYSTS

Parasitic cysts are considered in Chapter 29. The most important is cysticercosis, the larval form of *Taenia solium*, which may present as one or more subcutaneous cysts³⁷⁷ (see p. 762). Sparganosis may also present as a subcutaneous ‘cyst’ (see p. 763).

PHAEOMYCOTIC CYSTS

A phaeomycotic cyst (phaeohyphomycosis) is a subcutaneous cystic granuloma resulting from infection by hyphae with brown walls.³⁷⁸ A wood splinter is sometimes present in the lumen and is the source of this opportunistic fungus (see p. 704).

Figure 16.27 Omphalomesenteric duct cyst. Intestinal epithelium extends to the epidermal surface. The adjacent epidermis is markedly acanthotic. (H&E)

Figure 16.28 Mucocoele. There is a large mucinous pool. There is no epithelial lining in these cysts. (H&E)

DIGITAL MUCOUS CYST

A digital mucous cyst is usually found as a tense cystic nodule at the base of the nail of a finger or thumb. A second type (myxoid cyst) overlies a distal interphalangeal joint.³⁷⁹ The latter type resembles a ganglion, whereas the former resembles focal mucinosis. Digital mucous cysts are considered in detail with other mucinoses (see p. 414).

MUCOUS CYST (MUCOCELE)

Mucous cysts, found usually on the lower lip or buccal mucosa, result from the rupture of a duct of a minor salivary gland with extravasation of mucus. Large mucinous pools are formed with a variable inflammatory and fibroblastic response (**Fig. 16.28**). These lesions are considered with the mucinoses (see p. 416).

Figure 16.29 Metaplastic synovial cyst. A slit-like cavity lined by synovium is present adjacent to an area of scar tissue in the dermis. (H&E)

METAPLASTIC SYNOVIAL CYST

Metaplastic synovial cysts are intradermal or subcutaneous cysts lined by a membrane that resembles hyperplastic synovium.^{380–382} The lesions usually arise in surgical scars or at sites of trauma,³⁸³ unrelated to joints or other synovial structures.³⁸¹ Constant, chronic pressure was suspected of being the cause of a metaplastic synovial cyst arising in the area of the first metatarsal head.³⁸⁴ Cutaneous fragility and anomalous scarring may be the explanation for the cases that have developed in patients with Ehlers–Danlos syndrome.^{385,386} They are usually solitary.³⁸⁷

Histopathology^{380,381}

The cyst lining resembles hyperplastic synovium with partly hyalinized synovial villi. Sometimes only slit-like spaces lined by synovium are present (Fig. 16.29). The cystic cavities may communicate with the surface epidermis.

PSEUDOCYST OF THE AURICLE

Pseudocyst of the auricle is an uncommon, asymptomatic, non-inflammatory, intracartilaginous lesion affecting the upper half or third of the ear, most often in young or middle-aged males.^{388–391} It appears to be more common in men of Chinese or European ancestry.³⁹² Bilateral involvement has been reported.³⁹³ There is usually no clearcut history of preceding trauma.^{394,395} An association with atopic dermatitis of the face and ears has been noted, but it is quite rare.³⁹⁶ Ischemia has been suggested as a possible cause of the cartilaginous degeneration that is followed by the accumulation of yellowish fluid to form a pseudocyst.³⁹⁷ The term ‘seroma’ has been used for a closely related entity in which the accumulation of fluid was thought on clinical grounds to be outside the cartilage.³⁹⁸ Recurrence after treatment is not uncommon.^{399,400}

Histopathology

There is an intracartilaginous cavity without an epithelial lining.^{388,390} The wall is composed of eosinophilic, amorphous material that may contain smaller clefts (Fig. 16.30). There is focal fibrosis within the cavity, particularly at the margins, and this probably increases with the duration of the lesion.

Figure 16.30 (A) Pseudocyst of the auricle. (B) A cavity is present within the cartilage of the ear. Some operative hemorrhage is also present. (H&E)

ENDOMETRIOSIS

Endometriosis may be found in the umbilicus; in operation scars of the lower abdomen, particularly those associated with cesarean sections; and, rarely, in the inguinal region, thighs, and neck.^{401–409} It is confined to females. In one large series, the median age was 32 years.⁴⁰⁹ Cutaneous endometriosis accounts for less than 1% of cases of ectopic endometrial tissue. The endometrium in most lesions responds to the normal hormonal influences of the menstrual cycle.⁴¹⁰ It presents as a bluish-black tumor of the umbilicus that enlarges at approximately the time of the menses. There may be an associated bloody discharge from the lesion. Most lesions measure 1–3 cm in diameter. Endometriosis arising in scars is usually less well delineated. Such lesions are only partly cystic.

Theories of etiology include implantation, coelomic metaplasia, lymphatic dissemination, and hematogenous spread.

Histopathology⁴⁰⁵

There are multiple endometrial glands with surrounding endometrial stroma (Fig. 16.31). In keeping with müllerian epithelium, a broad spectrum of metaplastic changes may be present, including tubal, hobnail, oxyphilic, papillary syncytial, and mucinous metaplasia.⁴⁰⁹ The glands may show the usual cyclical changes of the endometrium. Decidualization of the stroma is occasionally present, and when this

Figure 16.31 Endometriosis of the umbilicus. Glands and stroma are set in fibrous tissue. The glands are functional with some luminal hemorrhage. (H&E)

comprises a substantial portion of a lesion, it is sometimes termed cutaneous deciduiosis.⁴¹¹⁻⁴¹³ The cells in decidualized stroma are epithelioid in type with abundant eosinophilic cytoplasm, and their presence can sometimes raise concerns for malignancy (Fig. 16.32); they are positive for vimentin, CD30, and CD10, and they are negative for S100 protein and pancytokeratin.^{413,414} Smooth muscle metaplasia is found in nearly one-third of all cases.⁴⁰⁹ The glands show variable cystic dilatation and may contain blood or debris. There is usually hemosiderin pigment in the functioning cases.⁴¹⁵ There may be dense fibrosis between the endometriotic foci. Adenocarcinoma and complex hyperplasia of the glands have been reported as very rare complications.^{409,416} Cells corresponding to the large granular lymphocytes of the endometrium are not uncommonly seen in immunostains for CD56.⁴⁰⁹ Glandular epithelium expresses estrogen and progesterone receptors, and the interstitial cells surrounding glandular tissue stain positively for CD10.^{417,418}

CUTANEOUS ENDOSALPINGIOSIS

Endosalpingiosis refers to the aberrant growth of fallopian tube epithelium outside its normal location. Its occurrence in the skin is very

Figure 16.32 Endometriosis with decidualized stroma. Decidualized cells are epithelioid in type and have abundant, eosinophilic cytoplasm. (H&E)

rare, with only four cases reported to date.^{281,419,420} Many cases probably go unreported. In one case, there were multiple papules around the umbilicus following salpingectomy.²⁸¹ The other three were solitary nodules in the umbilicus. Two patients had abdominal pain, and the other two were asymptomatic. Two cases followed cesarean section.^{419,420}

Histopathology

In the patients with a solitary nodule, there was a unilocular cyst with papillary projections into the lumen. The lining was composed of columnar epithelium, some ciliated and some secretory in type. Similar features were present in the case with multiple cysts that had some granular material in the lumen. The cysts were surrounded by fibrous tissue and sparse chronic inflammatory cells. There was no endometrial stroma. Tubal metaplasia is a common finding in cutaneous endometriosis, but it is only focal in distribution.⁴⁰⁹ A combination of endosalpingiosis and endometriosis has been reported in a cutaneous scar in the inguinal region, 10 years following myomectomy.⁴²¹

LYMPHATIC CYSTS

CYSTIC HYGROMA

Cystic hygroma usually presents as a cystic swelling of the subcutaneous tissue of the lower neck of neonates and infants. It is a variant of lymphangioma with large cavernous spaces in the subcutis lined by flattened endothelium (see p. 1076). Islands of connective tissue and sometimes smooth muscle are found between the channels.

SINUSES

Sinus tracts may develop in relation to infected wounds, acne,⁴²² inflamed and ruptured cysts, in association with thyroglossal or branchial cleft vestiges or defective closure of the neural tube,^{423,424} chronic osteomyelitis, and various chronic infections such as tuberculosis, mycetomas, and actinomycosis. A developmental posterior enteric sinus has been reported without any associated spinal dysraphism.⁴²⁵ A related vestige is the tailgut cyst, which presents as a subcutaneous tumor in the coccygeal region.⁴²⁶ The sinuses reported in association with heterotopic salivary gland tissue in the lower neck were probably of branchial cleft origin.⁴²⁷ The congenital peristernal

dermal sinus is of unknown origin.⁴²⁸ Three sinuses of dermatopathological importance are the congenital midline cervical cleft, the cutaneous dental sinus, and the pilonidal sinus. The preauricular sinus (see later) is regarded by some as a pit; it bridges these two categories.

CONGENITAL MIDLINE CERVICAL CLEFT

This rare anomaly of the ventral neck presents with a longitudinal opening along the midline that varies in length and width. The cleft is often weeping at birth; later there is scar formation if the cleft is not corrected surgically. There may be associated thyroglossal and branchial cleft anomalies. Its origin is disputed, although aberrant fusion of the branchial arches is favored.⁴²⁹ An example clinically resembling linear morphea has been described.⁴³⁰

Histopathology

The cleft is covered by stratified squamous epithelium with overlying parakeratosis. The underlying dermis may be atrophic. Dense fibrous tissue may be present and often extends into the subcutis. The sinus tract associated with this condition (often at its caudal end) is usually lined with respiratory-type epithelium. Sometimes a fibrous cord overlies the defect. It may include interfasciculated bundles of skeletal muscle.^{429,431}

CUTANEOUS DENTAL SINUS

An intermittently suppurating, chronic sinus tract may develop on the face or neck as a result of a chronic infection of dental origin.^{432–435} This is usually an apical abscess. The sinus tract openings typically present as nodulocystic papules, usually with purulent discharge.⁴³⁶ They most commonly occur on the chin and jaw (80%), but they may open within the nose and around the nasolabial folds.⁴³⁶

Histopathology

The sinus tract is lined by heavily inflamed granulation and fibrous tissue. An epithelial lining is sometimes present in part of the tract in cases of long standing. There are no grains as seen in actinomycosis. Rarely, a squamous cell carcinoma may develop from this epithelium.⁴³²

PILONIDAL SINUS

Pilonidal sinus occurs most commonly as a sinus in the sacrococcygeal region of hirsute males.⁴³⁷ Other sites include the umbilicus,⁴³⁸ axilla, scalp,⁴³⁹ ear,⁴⁴⁰ nose,⁴⁴¹ eyelid, genital region, the interdigital region of the foot,⁴⁴² and the finger webs of barbers' hands. It is surprisingly uncommon in female hairdressers.⁴⁴³ It is rare in shearers and dog groomers.⁴⁴⁴ Sometimes small cysts may be found in the scalp following hair transplants.⁴⁴⁵

Malignancy, usually a squamous cell carcinoma, may develop as a rare complication in lesions of long standing.⁴⁴⁶ An incidental cellular blue nevus has been reported in the wall of a pilonidal sinus.⁴⁴⁷

Histopathology

There is usually a sinus tract lined by granulation tissue, with areas of stratified squamous epithelium in the wall in approximately half the cases. This leads to a bulbous expansion in the lower dermis and subcutaneous tissues where there is a chronic abscess cavity. This contains one or more hair shafts that may be in the lumen, in branches of the main cavity, or in the wall itself (Fig. 16.33). There are usually foreign body granulomas in the vicinity of the hairs. There is variable fibrosis in the wall of the sinus and the deeper cavity.

Figure 16.33 Pilonidal sinus. (A) There is a chronic inflammatory infiltrate surrounding a chronic abscess containing hair shafts. (B) The hairs are lying free in the chronic 'abscess'. (H&E)

Rarely, the glomus coccygeum, a glomus body lying close to the tip of the coccyx, may be an incidental finding in the tissue surrounding a pilonidal sinus removed from this region.⁴⁴⁸

PITS

Pits are depressions in the epidermal surface. They may be found on the palms in pitted keratolysis (see p. 648), punctate keratoderma (see p. 295), reticulate acropigmentation of Kitamura (see p. 337), and chronic arsenicism. Pits can occur on the lip in the condition known as congenital lower lip pits (see later) and in the Kabuki makeup syndrome, oral-facial-digital syndrome type 1,⁴⁴⁹ and the popliteal pterygium syndrome.⁴⁵⁰ The latter syndrome appears to be allelic with Van der Woude syndrome (see below).^{450,451} Pigmented pits may arise in the perioral region in Dowling–Degos disease (see p. 337). Preauricular sinuses (ear pits) are manifest as small dells adjacent to the external ear (see below).

Bi-acromial dimples, also known as 'supraspinous fossae', are an anatomic variation that are not uncommon.⁴⁵² They are underdiagnosed.

CONGENITAL LOWER LIP PITS

Congenital lower lip pits (Van der Woude syndrome; OMIM 119300) is a rare autosomal dominant condition characterized by depressions and sometimes sinuses in the vermillion zone of the lower lip.^{449,453,454} The pits are usually bilateral; rarely, they are solitary.⁴⁵⁵ There is a frequent association with cleft lip and/or cleft palate. They should not be confused with the lip fissures seen in Down syndrome.⁴⁵⁶ The gene responsible, the interferon regulatory factor-6 (*IRF-6*) gene, has been mapped to the long arm of chromosome 1 (1q32–q41).^{450,453} A second locus (type 2; OMIM 606713) has been mapped to 1p34. Other loci seem likely.

Histopathology^{449,453}

There is a depression/invagination in the epidermis with some thinning in the base (Fig. 16.34A). A zone of parakeratosis is often present at either side of the pit. Sometimes a small fistula leads from the base of the pit to underlying minor salivary glands (Fig. 16.34B). There is usually no significant inflammation.

PREAURICULAR SINUS (EAR PITS)

Preauricular sinuses are a common congenital abnormality (despite the paucity of reports), occurring in up to 1% of infants; its incidence is higher in areas of Africa. They are small dells adjacent to the external ear near the ascending limb of the helix. They are more common on the right side, but they may be bilateral.⁴⁵⁷ They may be sporadic or inherited, the latter occurring as an autosomal dominant trait with incomplete penetrance and variable expression.⁴⁵⁷ They can be associated with hearing disorders and renal abnormalities. They may be present in branchial cleft anomalies.⁴⁵⁷

The branchio-oto-renal (BOR) syndrome (OMIM 113650) is associated with these sinuses. It is caused by mutations in the human *EYA1* gene on chromosome 8q13.3.⁴⁵⁷ A second form of this syndrome (OMIM 610896) is due to a mutation in the *SIX5* gene.

Histopathology

The sinus is lined by stratified squamous epithelium that may show some hyperkeratosis or parakeratosis.⁴⁵⁷ Sebaceous glands may be present in the wall. A variable inflammatory cell infiltrate may be present.

INTRODUCTION

The panniculus adiposus (subcutaneous fat) is a metabolic depot that also functions as a layer of insulation and as a buffer to trauma. It is composed of mature lipocytes, which are round to polygonal cells with an eccentric nucleus and a large cytoplasmic lipid vacuole.¹ In contrast, fetal fat cells contain multiple small lipid vacuoles. The lipocytes are separated from their neighbors by an inconspicuous matrix.²

The panniculus adiposus is divided into lobules by fibrous septa, which are continuous with the dermis. Smaller microlobules have been described within the larger lobules, but these smaller units are not of pathological importance. Within the fibrous septa run the small arteries and arterioles, venules, lymphatics, and nerves. The nutrient artery supplies the center of the lobule with drainage to venules in the fibrous septa.² As a consequence, interference with the arterial supply results in diffuse changes within the lobule (lobular panniculitis) while venous disorders are manifested by alterations in paraseptal regions (septal panniculitis).²

This chapter is concerned primarily with the inflammatory lesions of the subcutaneous fat – the panniculitides. Miscellaneous infiltrates and deposits are mentioned briefly.

Inflammatory lesions of the subcutaneous fat can be classified into three distinct categories:

- Septal panniculitis
- Lobular panniculitis
- Panniculitis associated with large vessel vasculitis.

Within each group, the histological appearances will depend on the stage of the disease at which the biopsy is taken. In early lesions, there are often neutrophils in the inflammatory infiltrate, whereas later lesions have a chronic infiltrate composed predominantly of lymphocytes but with a variable admixture of giant cells and lipid-containing macrophages. At an even later stage, there is some fibrosis. Accordingly, attempts at subclassifying the panniculitides on the basis of the predominant pattern of inflammation or cell type are largely unsuccessful, except for those with abundant eosinophils.

Inflammation of small venules will result in a *septal panniculitis* with some spillover of the inflammatory process into the lower dermis.² Involvement of the arterial supply, for example by vasculitis, will produce a *lobular panniculitis*. There are other mechanisms involved in some of the diseases that result in a lobular panniculitis. These are considered in the appropriate sections. The panniculitis associated with large vessel involvement, such as polyarteritis nodosa and migratory thrombophlebitis, is usually localized to the immediate vicinity of the involved vessel. It often has mixed lobular and septal features.

Unless an adequate biopsy is received, it may be difficult to reach a specific diagnosis.^{3,4} A diagnosis of 'lobular panniculitis ? type' may have to suffice in these cases. Another problem with the panniculitides is the considerable confusion that exists in the literature.⁵ In some reports, it would seem that a diagnosis has been made on purely clinical grounds and the pathological findings have been ignored. Several reviews of the panniculitides have been published. They describe the diversity of histological appearances that can be seen in the various panniculitides.⁶⁻⁹

The histological features of the panniculitides are summarized in [Table 17.1](#).

SEPTAL PANNICULITIS

In septal panniculitis, the inflammatory reaction is centered on the connective tissue septa of the subcutaneous fat.⁷ If the lesions are of long standing or recurrent in the same area, the septa may be considerably widened with a corresponding reduction in the amount of

intervening lobular fat. There is often some spillover of inflammatory cells and macrophages into the adjacent fat lobule. In small biopsies, this spillover of inflammatory cells can be misinterpreted as a lobular panniculitis.

In addition to the diseases considered here, a septal panniculitis may be seen in some cases of factitial panniculitis (see p. 549), cellulitis (see p. 643), nephrogenic systemic fibrosis (see p. 410),¹⁰ microscopic polyangiitis (see p. 242), and hydroa vacciniforme (see p. 623). The septal panniculitis reported in a patient with cytomegalovirus infection was probably an infective panniculitis and not erythema nodosum.¹¹ It has also been recorded in a patient with cryoglobulinemia (see p. 224) and in patients receiving apomorphine infusion for Parkinson's disease.¹² The symmetrical panniculitis reported in a patient with Whipple's disease showed a septal panniculitis with numerous PAS-positive foamy macrophages infiltrating the septa.¹³

The causes of septal panniculitis are listed in [Table 17.2](#).

ERYTHEMA NODOSUM

Erythema nodosum is an acute, painful, erythematous, nodular eruption. The nodules, which range from 1 to 5 cm or more in diameter, are usually situated on the anterior aspect of the lower legs; more rarely, they occur on the arms, soles,¹⁴⁻¹⁶ or trunk. There may be associated fever, malaise, and arthralgia. The lesions subside after a period of approximately 2–6 weeks. Up to one-third of cases may recur. Erythema nodosum usually occurs in young adults, but childhood cases occur.¹⁷ Encapsulated fat necrosis ('mobile encapsulated lipoma') is a rare complication (see p. 551).¹⁸ Erythema nodosum may be associated with sarcoidosis,⁴ Sweet's syndrome,^{19,20} Behçet's disease,²¹⁻²³ celiac disease,²⁴ pernicious anemia,²⁵ inflammatory bowel disease, diverticulitis,²⁶ intestinal bypass syndrome,²⁷ eosinophilic esophagitis,²⁸ carcinomas,^{29,30} carcinoid tumor,³¹ leukemia,³² lymphoma,³³⁻³⁵ hairy cell leukemia,³⁶ actinic granuloma,³⁷ tularemia³⁸ or with streptococcal,⁴ staphylococcal,³⁹ meningococcal,⁴⁰ campylobacter,⁴¹ giardia,⁴² salmonella,⁴³ histoplasma,⁴ mycoplasma,^{44,45} chlamydial,⁴⁶ mycobacterial,^{47,48} dermatophyte,⁴⁹ sporotrichosis,⁵⁰ human immunodeficiency virus,⁵¹ or yersinia^{52,53} infections and multiple amoebic abscesses.⁵⁴ Various drugs have been incriminated,⁵⁵ including isotretinoin,⁵⁶ sulfonamides, penicillin, ciprofloxacin,⁵⁷ minocycline,⁵⁸ leukotriene-modifying drugs such as zileuton,⁵⁹ azathioprine,⁶⁰ propylthiouracil (a myeloperoxidase-ANCA-positive erythema nodosum),⁶¹ salicylates, iodides, gold salts, echinacea,⁶² hepatitis B vaccine,⁴⁴ capecitabine,⁶³ and also oral contraceptives.⁶⁴ A case of erythema nodosum was associated with assisted reproductive therapy with intramuscular progesterone.⁶⁵ The triad of erythema nodosum, bilateral hilar lymphadenopathy, and polyarthralgia (Lofgren syndrome) represents an acute, benign, and usually self-limiting form of sarcoidosis.⁶⁶ It is said to be the most common form of sarcoidosis in Spain. The erythema nodosum is present at the onset in most cases.⁶⁶ Radiotherapy may also trigger the onset of erythema nodosum.^{67,68} In approximately one-third of cases, the etiology is obscure. The association with Sweet's syndrome has been reported on a number of occasions;^{69,70} in one case, this was related to glandular tularemia,⁷¹ and in another case it was associated with sulfasalazine.⁷²

The pathogenesis of erythema nodosum is unknown, but it may represent an allergic response to infection or systemic disease. Reactive oxygen intermediates, released by primed neutrophils, may play a role in the pathogenesis.⁷³

In *erythema nodosum migrans* (subacute nodular migratory panniculitis), a centrifugally enlarging plaque with central clearing develops on the lower leg. It is usually solitary, but several lesions may exist.⁷⁴⁻⁷⁹

In *chronic erythema nodosum*, there are non-ulcerated lesions located mainly on the legs that may persist for years. There is no migratory tendency.⁸⁰

Table 17.1 Panniculitis: histopathological features

Disease	Histopathological features
Erythema nodosum	Septal panniculitis with paraseptal inflammatory wedges; neutrophils early; septal giant cells; Miescher's radial granulomas
Necrobiosis lipoidica	Fibrous septal widening; dermal granulomas and necrobiosis
Scleroderma	Fibrous septal widening; dermal or fascial thickening with parallel coarse collagen
Erythema induratum–nodular vasculitis	Lobular and septolobular panniculitis; vasculitis and granulomas; necrosis common
Subcutaneous fat necrosis of the newborn	Lobular panniculitis; needle-shaped clefts in fat cells
Sclerema neonatorum	Similar needle-shaped clefts (crystals), but no inflammation
Weber–Christian disease	Doubtful entity; lobular panniculitis; neutrophils early; abundant foam cells
α_1 -Antitrypsin deficiency	Lobular panniculitis; dermal liquefaction; suppuration; septal collagenolysis
Cytophagic histiocytic panniculitis	Lobular panniculitis; numerous histiocytes showing cytophagocytosis ('bean bag' cells)
Panniculitis-like T-cell lymphoma	Lymphocytic lobular panniculitis; pleomorphic lymphocytes of variable size that rim adipocytes; karyorrhexis; necrosis; sometimes angioinvasion and cytophagocytosis
Pancreatic panniculitis	Lobular panniculitis; ghost-like necrotic fat cells; peripheral nuclear dusting
Lupus panniculitis	Lobular panniculitis with prominent lymphocytes (lymphocytic lobular panniculitis); paraseptal lymphoid follicles in 50%; often basal lichenoid tissue reaction
Subcutaneous sarcoidosis	Lobular granulomas, 'naked' and tuberculoid; $\pm$ central necrosis; $\pm$ perigranulomatous fibrosis
Lipodystrophy	Subcutaneous atrophy; sometimes early mild lobular panniculitis
Lipedema	Hypertrophy of fat; thickened fibrous septa; edema and adipocyte degeneration
HIV-associated lipodystrophy	Non-inflammatory except for scattered lymphocytes and lipophages; atrophy of fat
Gynoid lipodystrophy	Lipohypertrophy with variable thickness of septa; fat herniated into lower dermis (may be gender-related)
Membranous lipodystrophy	Microcysts with lipomembranous (membranocystic) change; dense fibrosis between islands of 'fatty microcysts'
Lipodermatosclerosis	Infarction of fat lobules; lipomembranous change; late fibrosis; hemosiderin; pericapillary fibrin caps; early inflammatory stage
Factitial panniculitis	Mixed septal and lobular panniculitis; sometimes suppurative; foreign body giant cells
Traumatic fat necrosis	Overlap with above; fat cysts, fibrosis and sometimes hemosiderin
Encapsulated fat necrosis	Lobules of necrotic fat; thin fibrous capsule that is usually hyaline; lipomembranous change common
Infective panniculitis	Suppuration or granulomas or numerous eosinophils depending on etiology
Non-infective neutrophilic panniculitis	Neutrophilic lobular panniculitis; necrosis sometimes present, admixture of cells with chronicity
Eosinophilic panniculitis	Numerous eosinophils in a lobular panniculitis; sometimes flame figures or parasite present
Calciophylaxis	Lobular fat necrosis with calcification; calcification in small vessels; mixed inflammatory infiltrate
Miscellaneous	Urate crystals in gout; necrobiotic granulomas in subcutaneous granuloma annulare or rheumatoid nodules
Panniculitis secondary to large vessel vasculitis	Vasculitis of artery or vein; panniculitis localized around vessel

Table 17.2 Diseases associated with a septal panniculitis

Erythema nodosum
Erythema nodosum migrans
Necrobiosis lipoidica
Factitial panniculitis (some)
Nephrogenic systemic fibrosis
Cellulitis
Microscopic polyangiitis
Hydroa vacciniforme (lobular also)
Apomorphine infusion
Cryoglobulinemia
Whipple's disease
Cytomegalovirus infection
α_1 -Antitrypsin deficiency (rare cases)

Treatment for erythema nodosum includes non-steroidal anti-inflammatory drugs, corticosteroids, and potassium iodide. Chronic cases have been successfully treated with infliximab⁸¹ and with adalimumab.⁸⁰

Histopathology

Erythema nodosum is a septal panniculitis with small foci of inflammatory cells extending into the adjacent lobular fat (**Fig. 17.1**). In some cases, this spillover of cells is more marked and includes foam cells, sometimes associated with focal necrosis of fat cells adjacent to the septa. Lobular extension can be quite marked in the fasciitis–panniculitis associated with brucellosis.⁸² The center of the lobule is spared, allowing a distinction to be made from lobular panniculitis. There is also some extension of inflammatory cells into the adjacent lower dermis. In most biopsies, the septal infiltrate is predominantly lymphocytic, but there are variable numbers of giant cells, usually of foreign body type, as well as a few eosinophils and histiocytes (**Fig. 17.2**). Small nodules composed of spindle to oval histiocytes arranged around a minute slit may be found (Miescher's radial granulomas).^{7,83} Well-formed tuberculoid granulomas are rare. Eosinophils

Figure 17.1 Erythema nodosum. The inflammatory infiltrate is confined to the septa of the subcutis. (H&E)

are sometimes prominent; in fact, a subset of cases termed 'eosinophilic panniculitis' otherwise present clinically and microscopically as typical erythema nodosum.^{84,85}

In early lesions, neutrophils are usually present. They are numerous in the rare suppurative variant of erythema nodosum in which neutrophils extend into the adjacent lobule.^{86,87} The fibrous septa are widened with edema and some fibrinoid change in the earlier stages. Later, there are increased numbers of fibroblasts with some fibrosis.

Blood vessel changes are variable. There is usually prominent endothelial swelling of small septal vessels and sometimes of medium-sized veins. There is lymphocytic cuffing of septal venules. Sometimes a definite vasculitis is present, but by the time most biopsies are taken, only nonspecific vascular changes are found. In the erythema nodosum-like lesions of Behçet's disease, a vasculitis is present in most cases. It may be of lymphocytic or leukocytoclastic type.⁸⁸ The lesions are not always confined to the septa.⁸⁸ A recent study of 26 cases of erythema nodosum-like lesions in Behçet's disease by Misago *et al.* supports and expands on these findings.⁸⁹ Seven of their cases were clinically and histopathologically identical to traditional erythema nodosum; these tended to occur in women with relatively mild Behçet's disease. Nineteen others with erythema nodosum-like lesions had definite evidence

Figure 17.2 (A) Erythema nodosum. (B) The inflamed septum contains a number of multinucleate giant cells in addition to lymphocytes and eosinophils. (H&E)

of leukocytoclastic or lymphocytic vasculitis involving subcutaneous venules (8 cases) or phlebitis of muscular veins mimicking the image of polyarteritis nodosa (11 cases). These individuals tended to have more severe Behçet's disease, sometimes with gastrointestinal involvement, and their erythema nodosum-like lesions were prone to involve the arms as well as the legs and feature lobular or mixed septal-lobular panniculitis.⁸⁹

Thurber and Kohler have stressed the variability in the histological appearances of erythema nodosum.⁹⁰ They presented four cases that initially showed unusual features but that on subsequent biopsies showed typical findings. Two cases initially showed predominantly neutrophilic infiltrates with focal suppuration, as well as vasculitis of medium-sized arteries. The third case showed a lobular panniculitis with a predominantly lymphohistiocytic infiltrate, whereas the fourth case showed a mixed septal and lobular panniculitis with a polyclonal lymphohistiocytic infiltrate and a vasculitis.⁹⁰

In a case reported as 'neoplastic erythema nodosum', a B-cell lymphoma produced both a lobular and a septal panniculitis.³⁴ It is not erythema nodosum.

In *erythema nodosum migrans* (subacute nodular migratory panniculitis), the septa are markedly thickened and fibrotic (Fig. 17.3). Inflammation is usually mild, although multinucleated giant cells and granulomas may be conspicuous along the edge of the septa. Neovascularization is often present at the septal borders.

Electron microscopy

Ultrastructural examination has shown damage to endothelial cells of small vessels with some extension of inflammatory cells into the vessel walls.^{22,91}

Differential diagnosis

Histopathologically, the picture of a predominantly septal panniculitis usually limits the differential diagnosis and tends to exclude those conditions that are mainly lobular or mixed. Pancreatic panniculitis may show predominantly septal changes in its earliest stages, but eventually these lesions exhibit the characteristic fat necrosis, with saponification and 'ghost cell' formation. Infection-induced panniculitis can sometimes mimic erythema nodosum, but there are often more extensive neutrophilic infiltrates, cellular necrosis (including sweat

gland necrosis), vascular proliferation, and hemorrhage. Special staining for organisms and microbiologic studies may be helpful if infection is a serious consideration. Two other septal panniculitides differ in other respects: morphea panniculitis is accompanied by dermal sclerosis and atrophy of appendages, whereas α_1 -antitrypsin deficiency panniculitis features – among other things – liquefactive necrosis of fat lobules and early splaying of reticular dermal collagen by neutrophils. The changes in erythema nodosum migrans (subacute nodular migratory panniculitis) are also those of a chronic septal panniculitis. However, in contrast to more classic forms of chronic erythema nodosum, subacute nodular migratory panniculitis shows greater septal thickening, more prominent granulomatous inflammation along the borders of widened subcutaneous septa, the absence of phlebitis, and rare hemorrhage.

NECROBIOSIS LIPOIDICA

In necrobiosis lipoidica, the necrobiotic and granulomatous process, followed by fibrosis, may extend from the dermis into the subcutaneous septa, producing marked widening of these structures, which encroach on the fat lobules. This condition is considered further in Chapter 7 (p. 203).

SCLERODERMA

In scleroderma and its localized cutaneous variants (morphea), there may be extension of the process from the dermis into the subcutaneous fat. There is marked fibrous thickening of the septa, and often lymphoid collections are present at the junction of the thickened septa and the fat lobules (Fig. 17.4).⁹²

There are variants of morphea in which only the subcutaneous fat and/or fascia are involved. The terms subcutaneous morphea and morphea profunda are often used interchangeably for these variants, although morphea profunda has been proposed as the appropriate diagnosis when both fat and fascia are involved and subcutaneous morphea for cases with involvement of fat only (see p. 350). A panniculitis usually accompanies the fasciitis associated with eosinophilic fasciitis.⁹³ Septal fibrosis and hyalinization are obvious features. There are often small lymphoid collections but not lymphoid follicles with germinal centers. Plasma cells are usually present. They were the predominant cell type in two siblings with the disease.⁹⁴

A case of linear scleroderma with an intense plasma cell infiltrate in the dermis and subcutaneous fat has been reported.⁹⁵ Nodular aggregates of plasma cells were present in the fat lobules and the thickened interlobular septa. Scleroderma is considered further in Chapter 11 (pp. 348–354).

LOBULAR PANNICULITIS

In the lobular panniculitides, the inflammatory infiltrate is present throughout the lobule but there is often some septal involvement as well. There are many different causes of a lobular panniculitis, and many of these are histologically distinct.⁸ However, sometimes it is not possible to distinguish between the various etiological groups, in which case the histological diagnosis may have to be simply 'lobular panniculitis'.

ERYTHEMA INDURATUM–NODULAR VASCULITIS

Erythema induratum and nodular vasculitis were originally regarded as one entity. However, it has been the practice for approximately

Figure 17.3 Subacute nodular migratory panniculitis (erythema nodosum migrans). Marked septal thickening is apparent. There is chronic, partly granulomatous inflammation along the edges of the septa. (H&E)

Figure 17.4 Morphea panniculitis. (A) Fibrous thickening of subcutaneous septa is apparent. (B) Collections of lymphocytes and a few plasma cells are seen at the dermal-subcutaneous interface. (H&E)

the past 50 years to recognize two variants – one of presumptive tuberculous origin (erythema induratum, Bazin type) and the other of nontuberculous origin, known as nodular vasculitis or erythema induratum, Whitfield type.³ The tuberculous group was regarded as a tuberculid (see p. 653) on the basis of the persistent failure to culture *Mycobacterium tuberculosis* from lesional tissue or to see organisms on acid-fast stains. The tuberculous origin of the Bazin subtype was assumed on the basis of strongly positive reactions with the Mantoux test, the presence of active tuberculosis in other organs in some cases, and the favorable response of the skin lesions to antituberculous therapy.^{96–101}

The advent of polymerase chain reaction (PCR)-based methods has led to the detection of mycobacterial DNA in 30–80% of cases of erythema induratum–nodular vasculitis, defined on the basis of clinical presentation and a lobular granulomatous panniculitis on histology.^{102–107} However, a study of 10 cases in 2005 failed to demonstrate *Mycobacterium* of any species by PCR techniques.¹⁰⁸ Because no significant differences have been consistently demonstrated between

cases with detectable mycobacterial DNA and those without, it does not seem tenable to continue the separation of erythema induratum and nodular vasculitis.¹⁰⁹ After all, erythema nodosum has multiple etiologies (including tuberculosis), and it is considered as one condition.^{47,110} Thus, the wheel has turned full circle and once again there is a single (composite) entity. It has been suggested that patients presenting with this disease should have an ELISpot (T-SPOT.TB[®]) assay or the QuantiFERON[®] TB gold test for detecting active or latent tuberculous disease.^{111–113} These are assays that detect interferon- γ released by T cells in response to *Mycobacterium tuberculosis*-specific antigens.¹¹⁴

Erythema induratum–nodular vasculitis is characterized by recurrent crops of tender erythematous nodules, usually with a predilection for the calves, although the shins are sometimes involved as well. The nodules may coalesce to form one or more plaques. Uncommonly, lesions may develop in other sites such as the buttocks and arms. Although it was originally regarded as a disease of young adult females, a wide range of ages can be affected. Lesions occasionally ulcerate; they may heal with scarring.¹¹⁵

Erythema induratum–nodular vasculitis appears to be a disease of diverse etiologies, mycobacterial infection being one of them. The simultaneous occurrence of papulonecrotic tuberculid and erythema induratum has been reported on a number of occasions.^{116,117} Other infections may be involved, including hepatitis C^{118–120} and *Chlamydo-phila pneumoniae*.¹²¹ An association with ulcerative colitis¹²² and Crohn's disease¹²³ has been reported. Both erythema nodosum and a lobular panniculitis with vasculitis can be produced by brucellosis.¹²⁴ A paraneoplastic presentation has also been suspected.¹²⁵ The pathogenesis appears to involve a delayed hypersensitivity or Arthus-type reaction. Host responses may perpetuate the disease even after the infection has been cleared.¹⁰³

In cases suspected of having a tuberculous etiology, antituberculous therapy should be given.¹⁰¹ Clofazimine was successfully used in the management of treatment-resistant nodular vasculitis, but it was later associated with enteropathy, requiring discontinuation of the drug with subsequent flare of the nodular vasculitis.¹²⁶

Histopathology^{103,110,127–129}

The inflammatory changes are usually restricted to the subcutis and the lower dermis. There is a lobular or septolobular panniculitis, usually diffuse, with varying combinations of granulomatous inflammation, vasculitis, focal necrosis, and septal fibrosis (Fig. 17.5). As in other panniculitides, the histological changes will vary with the duration of the lesions.

Granulomas may be well developed and tuberculoid; occasionally, they show caseation necrosis. More often, the granulomas are poorly developed. Lipophage collections are usually present. The inflammatory infiltrate includes neutrophils, lymphocytes, and some plasma cells. Neutrophils predominate in areas of fat necrosis.

Vascular changes, which are present in approximately 90% of cases, involve all sizes of arteries and veins.¹³⁰ Involved vessels show endothelial swelling and a mixed inflammatory cell infiltrate in the wall and periadventitial tissues (Fig. 17.6). A necrotizing vasculitis is sometimes present, particularly in early lesions.

Although no histological feature consistently reflects a tuberculoid etiology, necrosis is slightly more common in this group. In the past, the presence of tuberculoid granulomas in the deep dermis, often around the eccrine glands, was regarded as suggestive of a tuberculous etiology.¹³¹ However, it is the absence of consistent differences that has resulted in the concept of a unified entity.¹³¹

As a rule, erythema induratum–nodular vasculitis involves many contiguous lobules, whereas cutaneous polyarteritis nodosa produces a more localized panniculitis restricted to the vicinity of the involved vessels.

Figure 17.5 (A) Erythema induratum–nodular vasculitis. (B) There is inflammation in the fat lobules and to a lesser extent in the septa. (H&E)

Figure 17.6 Erythema induratum–nodular vasculitis. There is a lobular panniculitis with focal necrosis. A small blood vessel shows fibrinoid change. (H&E)

Differential diagnosis

Erythema nodosum may show lobular involvement in its early stages, but this generally evolves into a picture of predominantly septal panniculitis; true vasculitis is uncommonly encountered, with the possible exception of cases associated with Behçet's disease, and caseous necrosis is not a feature. Perniosis can be difficult to distinguish from erythema induratum, but there is typically a history of cold exposure, and on microscopic examination the vessels often show 'fluffy edema' of their walls. Infection-induced panniculitis tends to demonstrate a more prominent neutrophilic component, granular basophilic necrosis, sweat gland necrosis, and proliferations of small vessels. In addition, organisms may be identifiable on special staining; we have seen a nodular vasculitis-like histopathologic image associated with *Nocardia* infection. Lupus panniculitis is typically less granulomatous, has a prominent lymphoplasmacellular infiltrate (as is generally the case for panniculitides associated with connective tissue diseases), shows mucinous deposits, and sometimes (in almost half of cases) has overlying epidermal and dermal changes typical of lupus erythematosus. Both polyarteritis nodosa and thrombophlebitis tend to show inflammation more obviously limited to the immediate perivascular zone, in contrast to the extensive lobular panniculitis often encountered in erythema induratum, often requiring a search for the vasculitic changes.

SUBCUTANEOUS FAT NECROSIS OF THE NEWBORN

Subcutaneous fat necrosis of the newborn is a self-limited condition, present at birth or appearing in the first few days of life.^{132–134} It is characterized by indurated areas and distinct nodules with a predilection for the cheeks, shoulders, buttocks, thighs, and calves.¹³⁵ Sometimes only solitary lesions are discernible. Lesions may be painful. Subcutaneous atrophy is a common complication.¹³⁶ Ulceration has been rarely described.¹³⁷ Hypercalcemia has been reported in some cases.^{138–142} Thrombocytopenia, hypoglycemia, and hypertriglyceridemia may also develop.¹⁴³ Lactic acidosis and hyperferritinemia were each present in one case.^{144,145} Obstetrical trauma, hypothermia (including therapeutic hypothermia),¹⁴⁶ asphyxia, and anemia have been incriminated in the etiology.¹⁴⁷ A study from Paris added failure to thrive, forceps delivery, macrosomia, and exposure to active or passive smoking during pregnancy.¹³⁶ Cases have been reported after hypothermic cardiac surgery,^{148,149} prostaglandin E administration, and maternal exposure to cocaine or calcium channel blockers.^{150,151} It has been suggested that trauma to fragile adipose tissue low in oleic acid and with a compromised circulation, followed by the release of hydrolases, leads to the breakdown of unsaturated fatty acids.¹³² It should be remembered that infant fat already has a greater ratio of saturated to unsaturated fatty acids than exists in adult fat.

Histopathology^{133,152,153}

There is a normal epidermis and dermis with an underlying lobular panniculitis. Focal fat necrosis is present, and this may lead to fat cyst formation. There is an inflammatory infiltrate of lymphocytes, histiocytes, foreign body giant cells, and sometimes a few eosinophils wedged between the fat cells (Fig. 17.7). Many of the fat cells retain their outline but contain fine, eosinophilic cytoplasmic strands and granules, between which are narrow clefts radiating from a point near the periphery of the cell (Fig. 17.8).¹⁵⁴ The clefts contain doubly refractile crystals, representing triglycerides, on frozen section. Similar fine, needle-like crystals can be seen in relation to some of the giant cells. Cases have been reported without the needle-like crystals.¹⁵⁵ Eosinophilic granules, presumably released from surrounding degranulating eosinophils, have been described in the cytoplasm of the multinucleated giant cells.^{154,156} In older lesions, there is some fibrosis between

Figure 17.7 (A) Subcutaneous fat necrosis of the newborn. (B) There is a lobular and paraseptal panniculitis with lymphocytes, macrophages, and multinucleate giant cells wedged between the fat cells. (H&E)

the fat cells and there may be foci of calcification. Diagnosis can be made by fine needle aspiration cytology.^{157,158}

Electron microscopy^{152,153}

There are intact and necrotic fat cells containing needle-shaped crystals arranged radially or in parallel. Dense granular material is also present in the necrotic fat cells, which are surrounded by macrophages.

Differential diagnosis

The extensive cutaneous involvement in sclerema neonatorum is usually distinguishable from the localized, self-limited process of subcutaneous fat necrosis, and on biopsy, inflammation in sclerema is minimal. Post-steroid panniculitis is microscopically indistinguishable from subcutaneous fat necrosis, but it arises in a distinctive clinical setting (see later).

SCLEREMA NEONATORUM

Sclerema neonatorum has a pathogenetic relationship to subcutaneous fat necrosis of the newborn and was at one stage regarded as a diffuse

form of the latter.¹⁵⁹ It is also characterized by intracellular microcrystallization of triglyceride in the subcutaneous and sometimes also in the visceral fat of preterm neonates. Sclerema neonatorum produces wax-like, hard skin that is also dry and cold. It is rarely seen these days, presumably because of improved neonatal care.

Histopathology

There are fine, needle-like crystals in the fat cells, but unlike subcutaneous fat necrosis of the newborn, there is very little inflammation, few giant cells, and no calcification (Fig. 17.9). The subcutaneous septa are often widened by edema, which might explain the 'wide intersecting fibrous bands' formerly reported. Fat cells have been reported as increased in size, but a personally studied case showed small, immature fat cells.

Differential diagnosis

In contrast to sclerema neonatorum, subcutaneous fat necrosis of the newborn is a more localized process with a generally favorable prognosis. Lesions of subcutaneous fat necrosis show a more prominent inflammatory infiltrate, and needle-shaped crystals in radial array

Figure 17.8 Subcutaneous fat necrosis of the newborn. In this image, needle-shaped clefts can be identified in lipocytes and within multinucleated giant cells. Similar findings are seen in post-steroid panniculitis. (H&E)

Figure 17.9 Sclerema neonatorum. Needle-shaped clefts are present within adipocytes. Inflammation is sparse. (H&E)

are frequently evident within giant cells, whereas in biopsies of sclerema neonatorum, the dermis and subcutaneous septa appear edematous, with increased amounts of mucin deposition. In a recently reported case, gemcitabine therapy for pancreatic adenocarcinoma in a 60-year-old man resulted in the formation of livedoid lesions and infiltrated plaques that on microscopic examination showed thrombotic microangiopathy with intermittent adipocyte necrosis, with some of these cells displaying a radial array of needle-shaped clefts that were nonrefractile with polarization microscopy. The clinical setting, small vessel occlusion, and sporadic nature of the crystal formation would seem to be distinctive features in this condition.¹⁶⁰

COLD PANNICULITIS (HAXTHAUSEN'S DISEASE)

Panniculitis may occur following exposure to severe cold, particularly in infants.^{161–164} This is related in part to the higher ratio of saturated to unsaturated fatty acids, resulting in a higher solidification point of infantile fat. Cold injury is also related to fluctuations in blood flow that occur with declining temperatures (the 'hunting phenomenon'),

ice crystal formation, and the changes that occur with thawing.¹⁶⁵ It has occurred in older children and on the thighs of women who have ridden horses in cold weather.^{166,167} In the latter instance, it has been suggested that tight pants may restrict the blood supply, contributing to the injury. The lesions are indurated, somewhat tender plaques and nodules.

Histopathology

There is a predominantly lobular panniculitis with a mixed inflammatory cell infiltrate. Changes are most marked near the dermosubcutaneous junction, where the vessels show a perivascular infiltrate of lymphocytes and histiocytes. Other changes can include neutrophilic infiltration and formation of foamy macrophages and poorly developed granulomas, along with mucin deposition, adipocyte necrosis, and microcyst formation. There is some thickening of vessel walls. There is overlap with the changes described in deep perniosis (see p. 267).¹⁶⁸

WEBER–CHRISTIAN DISEASE

The diagnosis of Weber–Christian disease has engendered more confusion in dermatopathology than practically any other.^{169–184} It has been applied by some to all cases of panniculitis with systemic symptoms or to all cases of fatal panniculitis with visceral involvement.¹⁷⁰ The term 'Weber–Christian disease' has been a convenient 'pigeon hole' for undiagnosable cases of panniculitis.¹⁸⁵

Weber–Christian disease was defined in the past as a rare disorder with recurrent subcutaneous nodules and plaques with a predilection for the extremities and buttocks, commonly associated with fever.¹⁸¹ It was said to have a short self-limited course or follow an unremitting course with a fatal outcome and visceral involvement.^{178,182,183}

In a review of 30 cases diagnosed as Weber–Christian disease at the Mayo Clinic, White and Winkelmann were able to reclassify the cases as other entities, such as erythema nodosum, factitial panniculitis, cytophagic histiocytic panniculitis, and post-phlebitic syndrome.¹⁸⁶ **The diagnosis should no longer be used.**

The term *Rothman–Makai syndrome* was regarded as a rare variant of Weber–Christian disease but without the fever and systemic symptoms. Despite a recent case report, this entity is thought to no longer exist.¹⁸⁷

Histopathology

Weber–Christian disease was diagnosed in the past as a lobular panniculitis with numerous lipophages. It is this latter feature, now known to occur in other panniculitides, that often took precedence as a marker of the condition.

α_1 -ANTITRYPSIN DEFICIENCY

α_1 -Antitrypsin deficiency (OMIM 107400) is a genetic disorder characterized by low serum levels of α_1 -antitrypsin. The gene (*PI*) encoding this protease inhibitor is situated at 14q32.1. There are at least 90 allelic variants of this condition. Twenty-eight of the 40 cases (70%) of panniculitis in which the phenotype had been determined (up to 2004) had the ZZ phenotype, but other phenotypes have been involved.^{184,188–190} Panniculitis may be an early sign of this deficiency, but most cases present during the third and fourth decades.¹⁹¹ The lesions begin as tender, erythematous, indurated, subcutaneous nodules that may be widely disseminated on the trunk, particularly the buttocks, or on extremities, especially the proximal limbs.^{174,176,189,191} They may be precipitated by childbirth and by trauma, including cryotherapy.^{192,193} It has been associated with the extravasation of clarithromycin.¹⁹⁴ Spontaneous ulceration with discharge of an oily fluid may occur. Ulceration is uncommon in the other panniculitides.

Different treatments have been used to control the cutaneous lesions, such as corticosteroids, dapsone, cyclophosphamide, colchicine, and doxycycline.¹⁹⁵ Two more recent therapies have included plasma exchange or a purified concentrate of α_1 -antitrypsin (Prolastin®).^{195–199}

Histopathology

There is usually an acute panniculitis, sometimes septal as well as lobular, with masses of neutrophils and some necrosis of fat cells.^{200–202} Neutrophils usually extend into the reticular dermis, producing a characteristic infiltrate between the collagen bundles (so-called ‘splaying of neutrophils’).²⁰³ Dissolution of dermal collagen with transepidermal elimination of ‘liquefied’ dermis may occur. There may also be collagenolysis of the fibrous septa of the subcutis, resulting in isolated adipocyte lobules.¹⁷⁶ Another characteristic feature is the presence of skip areas of normal fat adjacent to foci of severe necrotizing panniculitis.²⁰⁰ Occasionally, lobular panniculitis with fat necrosis alone occurs. Rarely, a septal panniculitis with a mixed infiltrate with a predominance of neutrophils occurs.¹⁸⁹ Destruction of elastic tissue may also be present.¹⁷⁴ Vasculitis is sometimes present in the subcutis. In later lesions, as well as in those from patients with intermediate levels of protease inhibitor deficiency, there may be collections of histiocytic cells and lipophages and variable fibrosis. Dystrophic calcification may develop.¹⁸⁴

Differential diagnosis

Su *et al.* extensively reviewed the microscopic differential diagnosis for this disorder.²⁰⁰ Entities that are of particular importance for consideration include traumatic (factitial) panniculitis, infection-induced panniculitis, pancreatic (enzymic) panniculitis, and erythema induratum (nodular vasculitis). Each of these may be associated with infiltrates that include neutrophils and varying degrees of necrosis. Findings that would tend to exclude α_1 -antitrypsin deficiency panniculitis include foreign material or large ‘Swiss cheese-like’ vacuolated spaces (traumatic panniculitis); microorganisms identified with special staining (infection-induced panniculitis); ‘ghost cells’ and saponification of fat (pancreatic panniculitis); or vasculitis involving a medium-sized subcutaneous vessel, sometimes with caseous necrosis (erythema induratum–nodular vasculitis).

CYTOPHAGIC HISTIOCYTIC PANNICULITIS

Winkelman and colleagues coined the term ‘cytophagic histiocytic panniculitis’ more than 30 years ago for a usually fatal syndrome that included a chronic and recurring panniculitis with an infiltrate of cytophagic histiocytes with eventual multisystem involvement, terminating usually with a hemorrhagic diathesis resulting from the hemophagocytic syndrome.^{172,204–215} Other cases have been included in the past with systemic Weber–Christian disease.¹⁷¹ The current status of this condition is controversial. Two distinct entities appear to be included under this ‘umbrella’ term: subcutaneous panniculitis-like T-cell lymphoma (see later) and an authentic panniculitis for which the term cytophagic histiocytic panniculitis still applies. In the latter group are several patients in whom the disease has not progressed to overt lymphoma after prolonged follow-up (41 years in one case).^{216,217} Furthermore, monoclonal T-cell populations cannot be detected in these cases, although parallels have been drawn with large plaque parapsoriasis in which this may also occur.²¹⁸ It is possible that isolated cases represent a manifestation of a non-neoplastic, infection-associated hemophagocytic syndrome.^{218–220} Fatal cases still occur in the presumptive non-lymphoma group.²²¹

The disease, as originally described, consists of ulcerating nodules or plaques, sometimes painful, with a predilection for the legs and

Figure 17.10 Cytophagic histiocytic panniculitis. Large macrophages have phagocytosed fragments of lymphocytes, accounting for the term ‘bean bag cells’. (H&E)

forearms. Other sites are often involved in established cases. It affects mostly middle-aged or elderly individuals.

Histopathology

There is a lobular panniculitis, sometimes with extension into the lower dermis.¹⁷² There may be fat necrosis, focal hemorrhage, and a nonspecific inflammatory infiltrate. The diagnostic feature is the presence of sheets and clusters of histiocytes showing prominent phagocytosis of red cells, white cells, and nuclear debris. Cells stuffed with phagocytosed materials have been called ‘bean bag’ cells (**Fig. 17.10**).¹⁷² Membranocystic change is uncommonly present.²²²

PANNICULITIS-LIKE T-CELL LYMPHOMA

Panniculitis-like T-cell lymphoma is a rare form of cutaneous lymphoma; more than 150 cases have now been reported.^{223–227} Affected individuals present with multiple subcutaneous tumors or plaques, often associated with constitutional symptoms. Unusual presentations include patches of alopecia²²⁸ and venous stasis-like ulceration.²²⁹ Most cases occur in adults, but children can be affected.^{230,231} Sometimes a cytokine-induced hemophagocytic syndrome develops.^{217,223} The disease is indolent in some,^{224,228} but it may run a rapid course. Most cases have the phenotype of cytotoxic T cells and are derived from $\alpha\beta$ T cells.²³² A case purporting to have resulted from previous chemotherapy has been reported.²³³ Another case developed in a cardiac allograft recipient.²³⁴

A panniculitis has also been reported in association with a lymphoma composed of natural killer cells.²³⁵ An association with Epstein–Barr virus is common in these CD56⁺, nasal-type lymphomas.^{223,236,237} They have an aggressive course, often terminating with a fatal hemophagocytic syndrome.²³⁸ This variant is derived from $\gamma\delta$ T cells.²³⁹ They bear a plasmacytoid dendritic cell phenotype.²⁴⁰

These types of cutaneous lymphoma are considered further in Chapter 41 (p. 1189).

Histopathology

There is a variable admixture of pleomorphic small, medium, or large lymphocytes and histiocytes infiltrating the subcutis in the pattern of

a lobular panniculitis (Fig. 17.11).²⁴¹ Neoplastic cells rim individual adipocytes in a lace-like pattern.²³² Fat necrosis and karyorrhexis occur in all cases, whereas cytophagocytosis and angioinvasion are sometimes seen.²⁴³

Differential diagnosis

Rimming of adipocytes by neoplastic cells is not specific for this entity but can also be seen in other lymphomas with cutaneous involvement.²⁴² In the nasal-type lymphomas of CD56⁺ natural killer cells, angioinvasion and necrosis are common.^{223,244} Furthermore, these lesions tend to be centered on the dermis with secondary involvement of the subcutis.

In recent years, attention has been drawn to cases of subcutaneous panniculitis-like T-cell lymphoma that presented with lichenoid (interface) changes, resembling lupus erythematosus panniculitis.²⁴⁵ Even mucin has been present in the dermis.²⁴⁶ Magro and colleagues have expressed the view that a spectrum of subcutaneous T-cell dyscrasias exists that includes lupus profundus, indeterminate lymphocytic lobular panniculitis, and subcutaneous T-cell lymphoma.²⁴⁷ In a series of 32 cases of lymphocytic lobular panniculitis, 19 cases were regarded as lupus profundus, 6 as indeterminate, and 7 as subcutaneous T-cell

lymphoma.²⁴⁷ In a later publication, this group introduced the term **atypical lymphocytic lobular panniculitis** for 12 patients, prospectively encountered, who presented with a lymphocytic panniculitis accompanied by atypia but not fulfilling the criteria for subcutaneous T-cell lymphoma.^{248,249} They had an indolent course. The majority of the cases showed clonal T-cell receptor- γ (TCR- γ) rearrangements.²⁴⁸ An editorial in response to this article, by McNutt and Fung, stated that this should be considered 'a provisional diagnosis', whereas a letter from Ackerman called this concept 'humbug on every score'. Suffice it to say that diagnostically difficult cases of lymphocytic lobular panniculitis are sometimes seen. Both the author and editor have seen several cases with initial lupus-like features that progressed to overt subcutaneous T-cell lymphoma.

PANCREATIC PANNICULITIS

Pancreatic panniculitis manifests as painful or asymptomatic subcutaneous nodules or indurated plaques on the thighs, buttocks, lower trunk, or distal extremities, usually the lower. The lesions are associated with acute or chronic pancreatitis,²⁵⁰⁻²⁵⁶ pancreatic pseudocysts, traumatic pancreatitis, or, less commonly, pancreatic carcinoma.²⁵⁷⁻²⁶⁰

Figure 17.11 (A) Panniculitis-like T-cell lymphoma. (B) There is a lobular panniculitis. There is atypia of lymphocytes, but this diagnosis is often missed in early lesions. (H&E)

The acute pancreatitis or pancreatic carcinoma may be asymptomatic.²⁶⁰⁻²⁶² Pancreatic panniculitis has been reported in a 4-year-old child with the nephrotic syndrome;²⁶³ in acute pancreatitis secondary to L-asparaginase treatment for acute lymphoblastic leukemia;²⁶⁴ in a patient with a pancreas divisum;²⁶⁵ and in association with HELLP syndrome (hemolysis, elevated liver enzymes, low platelet count), acute fatty liver of pregnancy, and pancreatitis.²⁶⁶ There may also be polyserositis, arthritis, eosinophilia, or rarely a leukemoid reaction. The pancreatic carcinoma, when present, is often of acinic type, although panniculitis has also been reported in association with an islet cell carcinoma.^{264,267-270}

Lesions probably result from the local action of blood-borne pancreatic lipase and trypsin, although other factors may also be involved.^{261,271} Cases have been reported without pancreatic disease but with circulating lipase or amylase of uncertain origin.²⁷²

Histopathology

Sections of established lesions show a lobular panniculitis involving much of the fat of the affected lobule. Sometimes, contiguous lobules show a different stage in the histological evolution of the process. Early lesions show enzymatic fat necrosis, with the ghost-like outline of fat cells remaining (Fig. 17.12). It has been suggested, on the basis of one case, that at an even earlier stage (2-day-old lesions) there is a septal panniculitis.²⁷³ Liquefaction with breakdown of fat cells will eventually occur. At the margins of the necrotic fat, there is a variable neutrophil infiltrate, usually mild, associated with nuclear dusting, fine basophilic calcium deposits, and some hemorrhage.²⁷⁴ The necrotic fat cells may also have a pale basophilic hue due to the deposition of calcium salts. In older lesions, there are giant cells, lipophages, lymphocytes, hemosiderin and other blood pigments, and eventual fibrosis. There may be some extension of the inflammatory process into the underlying dermis.

Differential diagnosis

The microscopic differential diagnosis of pancreatic panniculitis includes erythema nodosum, particularly in early stages in which there may be a neutrophilic septal panniculitis, infection-induced panniculitis, or subcutaneous Sweet's syndrome.²⁶⁶ In later stages, in which the infiltrate is more lobular or displays mixed cellularity, other conditions with similarities include α_1 -antitrypsin deficiency panniculitis or lupus panniculitis. The fat necrosis of α_1 -antitrypsin deficiency may have some resemblance to the ghost cells of pancreatic panniculitis, but 'skip areas' of uninvolved, apparently normal fat are not observed in pancreatic panniculitis. Lupus panniculitis is predominantly

lymphoplasmacytic, may feature mucin deposition or eosinophilic hyaline change, and can display overlying epidermal and dermal changes of lupus erythematosus; the granular or homogeneous basophilic necrosis typical of pancreatic panniculitis is not observed.

LUPUS PANNICULITIS

Lupus panniculitis (sometimes referred to as lupus (erythematosus) profundus) is a chronic, recurrent panniculitis with a predilection for the proximal extremities, trunk, or lower back. It is a complication in approximately 1–3% of patients with cutaneous lupus erythematosus, both systemic and discoid forms.²⁷⁵⁻²⁷⁹ Rare sites of involvement in Western populations include the scalp²⁸⁰ and the earlobe.²⁸¹ The face and scalp are common sites of involvement in Asians,²⁸² linear lesions of the scalp comprise a unique manifestation of lupus panniculitis that is common in, but not restricted to, East Asian populations.²⁸³⁻²⁸⁵ There is a female predominance. Although most cases develop in middle-aged adults, onset in childhood has been reported.²⁸⁶⁻²⁸⁹ The lesions present as subcutaneous nodules or indurated plaques, although large, painful, indolent ulcers may develop.^{290,291} Lipoatrophy may result. This was accompanied by localized hypertrichosis in one case.²⁹² The panniculitis may precede, accompany, or follow the development of the associated lupus erythematosus;²⁷⁸ in nearly half of the cases, no associated lupus subtype or autoimmune disease is present.^{293,294} Accordingly, lupus panniculitis should be regarded as a unique entity within the lupus spectrum.²⁹³ It has been suggested that a type I interferon-driven immune response may be responsible for the lesions.²⁹⁵ The lobular panniculitis is dominated by cytotoxic CXCR3⁺ lymphocytes.²⁹⁵

A panniculitis mimicking lupus panniculitis has been reported in a case of malignant atrophic papulosis (Degos' disease);²⁹⁶ many pathologists now regard malignant atrophic papulosis as being part of the 'lupus spectrum'. A lupus-like lobular panniculitis may develop at the injection site of glatiramer acetate, used in the treatment of multiple sclerosis.²⁹⁷

Treatment options include corticosteroids, cyclosporine (ciclosporin), dapsone, and antimalarials such as hydroxychloroquine.^{289,298} Topical treatment with potent corticosteroids may be used for localized lesions.

Histopathology

In up to half the cases, there are epidermal and dermal changes of lupus erythematosus (particularly in those complicating discoid lupus

Figure 17.12 (A) Pancreatic fat necrosis characterized by enzymatic fat necrosis surrounded by a zone containing nuclear dust and an inflammatory cell infiltrate. **(B)** The fat necrosis has a characteristic appearance. (H&E)

Figure 17.13 Lupus panniculitis. There are frequently overlying epidermal and dermal changes of lupus erythematosus, including, in this case, epidermal atrophy, thinning of lateral follicular walls, and periappendageal infiltrates. (H&E)

erythematosus), with basal vacuolar change and a superficial and deep perivascular lymphocytic infiltrate with perifollicular involvement (**Fig. 17.13**). The group from Graz, Austria, found dermal infiltrates in 82% of cases and mucin deposition in 73%.²⁹⁹ There is a lobular panniculitis with a prominent lymphocytic infiltrate (lymphocytic lobular panniculitis).^{225,276} Concomitant septal involvement is often present.²⁹⁹ A lymphocytic vasculitis with lymphocytic nuclear dust is sometimes present. A characteristic feature, found in 20–50% of cases, is the presence of lymphoid follicles, sometimes with germinal centers, adjacent to the fibrous septa (**Fig. 17.14**). Plasma cells are present in many cases, whereas eosinophils may be seen in up to 25% of cases.³⁰⁰ Lipophages may sometimes be quite numerous. Myxoid and hyaline change may be found in the connective tissue septa and lower dermis. Hyaline sclerosis may extend into the lobules. Sometimes there are calcium deposits in older lesions. Membranocystic (lipomembranous) changes may be present,^{293,301–303} and changes of cytophagic histiocytic panniculitis have been described in a few cases.³⁰⁴ Although it has been suggested that membranocystic change and calcification may be associated with systemic lupus erythematosus, this is apparently not always the case.³⁰⁵

Differential diagnosis

The main differential diagnosis is subcutaneous panniculitis-like T-cell lymphoma (SPTCL). Cases of this entity presenting as lupus

Figure 17.14 Lupus panniculitis. (A) Paraseptal lymphoid follicles are characteristic. (B) Lymphocytes extend into the adjacent fat lobules. (H&E)

erythematosus panniculitis have been well documented.³⁰⁶ The most useful criteria for distinguishing lupus panniculitis from SPTCL are the presence in lupus panniculitis of epidermal involvement, lymphoid follicles with reactive germinal centers, a mixed cell infiltrate with prominent plasma cells, clusters of B lymphocytes, and polyclonal TCR- γ gene rearrangement.²⁹⁹ In a recent comparative study, clusters of plasmacytoid dendritic cells (identified by immunohistochemical staining for CD123) were found to be a characteristic feature of lupus panniculitis and not SPTCL.³⁰⁷ Other distinguishing features found in that study included lymphoid follicles, dermal mucin, lesser degrees of cytologic atypia and a lack of adipocyte rimming by lymphocytes (lupus panniculitis), and different patterns of fat necrosis (hyaline and lipomembranous in lupus panniculitis and fibrinoid/coagulative in SPTCL).³⁰⁷ Unfortunately, dermal mucin can indeed be found in some cases of SPTCL. Lymphoid follicles are uncommon in other panniculitides, but they are occasionally seen in morphea, erythema nodosum, and erythema induratum–nodular vasculitis.³⁰⁸ In a recent study of two cases of cold-induced dermatitis due to ice-pack therapy, the authors noted microscopic features of cold panniculitis and perniosis that resembled lupus erythematosus; similarities to lupus erythematosus with panniculitis included basilar epidermal vacuolization, a perivascular and periadnexal dermal infiltrate, dermal mucin deposition, and a lobular lymphocytic panniculitis.³⁰⁹ Clusters of CD123⁺ plasmacytoid dendritic cells were also seen in these cases of cold-induced panniculitis, but the clusters were smaller than those associated with lupus panniculitis.³⁰⁹

CONNECTIVE TISSUE PANNICULITIS

Connective tissue panniculitis is extremely rare.³¹⁰ It tends to occur in female adults and children. It is characterized by multiple nodules and plaques on the trunk and lower limbs.^{310,311} Low-titer antinuclear antibodies are usually present. Cases followed by lipoatrophy have been included as a variant,^{312–316} this may be the natural course of the disease. Other autoimmune diseases or a family history of autoimmune disease may be present.³¹⁰

Histopathology

The reported cases have shown a lobular panniculitis with some fat necrosis resembling the appearance in erythema induratum–nodular vasculitis but showing no vessel changes and no granulomas. There have been dense lymphocytic infiltrates, rare lymphoid follicles, and small foam cell collections.^{310,311}

A pustular panniculitis has been reported in one patient with rheumatoid arthritis.³¹⁷

POST-STEROID PANNICULITIS

Post-steroid panniculitis is a rare complication of systemic corticosteroid therapy, classically when administered in the treatment for acute rheumatic fever. It is characterized clinically by the development, usually on the cheeks, of multiple subcutaneous nodules within days or weeks of the withdrawal of steroid therapy.^{318,319} It usually occurs when the steroid is abruptly tapered or stopped. Although most common in children, the condition has been reported in adults.³²⁰ The lesions heal without scarring and can actually continue to resolve if corticosteroids are readministered, but they can reappear if these agents are again withdrawn too rapidly.³¹⁸

Histopathology

There is a nonspecific lobular panniculitis with lymphocytes, histiocytes, and some foam cells and giant cells. Septal vessels are spared,

distinguishing the lesions from those of erythema induratum–nodular vasculitis. Needle-shaped clefts are present within adipocytes.³¹⁹

Differential diagnosis

Cold panniculitis, including popsicle panniculitis, may be clinically and histopathologically similar, but the history of cold exposure and lack of needle-shaped clefts permit distinction. The microscopic changes of post-steroid panniculitis are virtually identical to those of subcutaneous fat necrosis of the newborn. The clinical history again should be decisive, but in the absence of a history, findings such as calcification or hemorrhage are more suggestive of subcutaneous fat necrosis of the newborn.

SUBCUTANEOUS SARCOIDOSIS

Subcutaneous sarcoidosis is an uncommon form of sarcoidosis that presents with subcutaneous nodules, principally on the extremities. It constituted 2.2% of the cases of cutaneous sarcoidosis on file at the Mayo Clinic.³²¹ This entity should not be confused with the erythema nodosum that may be associated with sarcoidosis, particularly in cases of Lofgren syndrome (see p. 532). Sarcoidosis is discussed further in Chapter 7 (pp. 191–194).

Histopathology

The granulomas are lobular in distribution. There is usually some perigranulomatous fibrosis, but this usually spares the septae. Whereas many of the granulomas are so-called ‘naked’ in type, others are more tuberculoid with a rim of lymphocytes. This feature is typical of the subcutaneous form.³²² There may be some necrosis at the center of the granulomas, simulating tuberculosis.⁸ Calcification may also be present.

LIPODYSTROPHY SYNDROMES

The term ‘lipodystrophy’ has traditionally been used for primary, idiopathic atrophy of subcutaneous tissue, whether *total*, *partial*, or *localized*.³²³ It has been distinguished from the secondary lipoatrophy that may follow certain panniculitides, such as lupus panniculitis, connective tissue panniculitis, and subcutaneous morphea.^{313,323–326} Lipoatrophy may be a diagnostically challenging presentation of T-cell lymphoma.³²⁷ The term ‘lipodystrophy’ is also used for the lipoatrophy (and the rare lipohypertrophy) that may follow the repeated injection of insulin into the subcutis by diabetics.³²⁸ The term ‘corticosteroid-induced lipodystrophy’ has been used for the morphological changes that follow the use of corticosteroids.³²⁹ Adipose tissue accumulates in the face (‘moon’ face), the dorsocervical region (‘buffalo hump’), the supraclavicular area, and the abdomen.³²⁹ It has been suggested that lipedema, characterized by the abnormal deposition of subcutaneous fat in the legs (associated with edema), is a lipodystrophy.³³⁰ The three major categories of lipodystrophy are considered further, followed by a discussion of lipedema.

Total lipodystrophy

Total lipodystrophy may be congenital or acquired. *Congenital* generalized lipodystrophy (Berardinelli–Seip syndrome) is an autosomal recessive disorder with complete loss of adipose tissue at birth, with the exception of the adipose tissue of the orbits, palms, soles, vulva, breast, and tongue.³³¹ There are at least three types: type 1 (OMIM 608594), which is caused by a mutation in the gene encoding 1-acylglycerol-3-phosphate O-acyltransferase-2 (AGPAT2) on chromosome 9q34.3;³³² type 2 (OMIM 269700), which is caused by a mutation in the gene encoding seipin (BSCL2) located at 11q13,³³³ and a third locus, caveolin-1 (CAV1), which has been identified in an adolescent

female.³³⁴ The genetic basis of a fourth novel subtype remains to be determined.³³⁴

Acquired generalized lipodystrophy (Lawrence syndrome) is associated with metabolic disturbances such as diabetes or endocrine disorders.²⁷⁷ A case triggered by pulmonary tuberculosis has been reported.³³⁵

Partial lipodystrophy

Partial lipodystrophy usually begins with symmetrical loss of facial fat, often progressing to involve the upper trunk and arms.³³⁶ It may be familial or acquired. The *familial* variant (Dunnigan type) is discussed after the acquired type, which is more common. Two variants of *acquired partial lipodystrophy* (Barraquer–Simons disease) have been described. In the *Weir–Mitchell type*, there is loss of fat from the face, with or without atrophy of the arms and upper trunk, whereas in the *Laignel–Lavastine type* there is concomitant hypertrophy of the fat of the lower part of the body.³³⁷ Unilateral variants of this have been described,^{338,339} facial hemiatrophy is known as the Parry–Romberg syndrome.^{338,340} Cases of partial lipodystrophy have been related to thyroid disease, extrinsic allergic alveolitis,³⁴¹ acanthosis nigricans, dermatomyositis,^{342,343} localized scleroderma,³⁴⁴ myasthenia gravis, the antiphospholipid syndrome,³⁴⁵ membranoproliferative glomerulonephritis,^{346–348} C3 hypocomplementemia,³⁴⁹ lupus erythematosus and vitiligo together with hypothyroidism,³⁵⁰ hepatitis B infection,³⁵¹ and recurrent infections.²⁷⁷ Infundibulocystic proliferations occurred on the finger in one case.³⁵² An acquired lipodystrophy was reported in a 3-year-old girl in whom additional material was detected on chromosome 10 at the 10q26 location, at the site of the human pancreatic lipase gene.³⁵³ However, most cases of acquired partial lipodystrophy probably have an immunological mechanism.

Familial partial lipodystrophy (Dunnigan type; OMIM 151660) is an autosomal dominant disorder with normal adipose distribution in childhood. Gradual loss of fat from the extremities and trunk and increased fat deposition on the face and neck begin at puberty.³³¹ It is one of the nine laminopathies caused by mutations in the *LMNA* gene that encodes the nuclear envelope proteins lamin A and lamin C.³⁵⁴ The gene has been mapped to chromosome 1q21–q22. Other disorders of this gene, discussed in this book, result in progeria of Hutchinson–Gilford type (see p. 378) and restrictive dermopathy (see p. 373).

Localized lipodystrophy

Localized lipodystrophy is characterized by annular or semicircular areas of atrophy, often solitary. It needs to be distinguished from morphea-related lipoatrophy.³⁵⁵ Variants have been described near the ankles,^{213,356–358} on the thighs,^{214,359,360} over the sacrum,³⁶¹ on the abdomen (lipodystrophia centrifugalis abdominalis),^{362–371} and in the form of a unilateral linear panatrophy of the extremities.³⁷² In a series of 30 Korean patients with lipodystrophia centrifugalis abdominalis, 4 were adult women, 20 were girls, and 6 were boys.³⁷¹ The mean age of onset was 6.2 years. White people are uncommonly affected.³⁷³ ‘Post-injection’ lipoatrophy is another variant of localized lipodystrophy. It can follow the injection of corticosteroids,³⁷⁴ methotrexate,³⁶⁰ iron dextran, vaccines,³⁷⁵ insulin, and penicillin.^{376–378} The injection of glatiramer acetate for the treatment of multiple sclerosis produces a lobular panniculitis that may resemble lupus panniculitis.²⁹⁷ In one series of localized lipoatrophy, 9 of the 16 patients had received injections at the site.³⁷⁹ Pressure and microtraumas appear to be involved in the causation of some other cases of the localized variant, particularly semicircular lipoatrophy.^{359,380–383} Leg crossing is another cause of dimpling and localized lipoatrophy. It produces pressure in the area that rests on the patella of the opposing knee.³⁸⁴ Hyperpigmented circumferential bands may develop as a consequence of wearing tight socks. There is no evidence that lipoatrophy is present in these cases.³⁸⁵

Linear atrophic patches have been reported as a manifestation of the complex regional pain syndrome.³⁸⁶ Apoptosis of fat cells has been noted during the lipoatrophic process in one case of abdominal lipodystrophy.³⁸⁷

Lipedema

Lipedema is characterized by diffuse, bilaterally symmetrical, enlargement of the buttocks and legs due to the subcutaneous deposition of fat.³⁸⁸ The feet are much less involved or spared entirely.³⁸⁹ There is some clinical resemblance to lymphedema. Women are almost exclusively involved, with the lipedema typically developing insidiously after puberty.³⁸⁹ Approximately 10% of women may be affected to some degree. It occurs independently of lymphatic or venous insufficiency.

The histopathology of the three major categories of lipodystrophy and that of lipedema are considered together.

Histopathology

In established cases, there is atrophy of subcutaneous fat and usually no evidence of inflammation. In some cases, biopsy of an early lesion shows a lobular panniculitis, often with some vascular involvement.^{390–394} In one personally studied case, there was a lobular panniculitis with numerous foam cells, small fat cysts, and some lymphocytes; there was no vasculitis (Fig. 17.15). This patient had partial lipodystrophy with prominent facial involvement and a poorly characterized connective tissue disease. Her inflammatory lesions were transient.

It has been suggested that there are two histopathological types of lipodystrophy, but whether this is always stage related (discussed previously) has not been clarified.³⁹⁰ In one group, there are prominent involutional changes to the subcutaneous fat with small lipocytes and intervening hyaline or myxoid connective tissue containing numerous capillaries (Fig. 17.16). The second group has inflammatory changes characterized by a lobular panniculitis with lymphocytes, lipophages, and plasma cells. This pattern was present in the young girl with abnormalities of chromosome 10 (discussed previously). A dermal lymphocytic vasculitis has also been described.³³⁷ The inflammatory type usually has multiple areas of lipoatrophy clinically and immunoreactants in blood vessels or the basement membrane on direct immunofluorescence.

The *localized variants*, such as semicircular and post-injection lipoatrophy, are infrequently biopsied. They show loss of fat with diminutive fat lobules within a partially fibrosed stroma.³⁷⁴ There is usually no evidence of panniculitis, although inflammation has been reported.³⁹⁵ Striking periecrine inflammation of lymphocytic type was present in one case.³⁹⁶ Occasional macrophages may be seen in close proximity to lipocytes. They appear to engulf segments of altered adipose tissue and stroma.³⁷⁴ There are often scattered lipophages.^{379,380} Epidermal atrophy and dermal fibrosis sometimes accompany the changes in the fat.³⁹⁷ The appearances can resemble embryonic fat. Most cases correspond to the first group mentioned previously.

In *lipedema*, there is marked circumferential enlargement of the subcutaneous tissue due to fatty hypertrophy. Fat lobules are surrounded by thickened fibrous septa. There may be some edema and adipocyte degeneration.³⁸⁸ Pseudoxanthoma-like changes were present in the subcutis in one case (Fig. 17.17).³⁸⁸

HIV-ASSOCIATED LIPODYSTROPHY

A lipodystrophy can be seen in patients with AIDS. Three clinical settings appear to be involved. The most common variant, characterized by the presence of peripheral lipoatrophy and central adiposity,

Figure 17.15 (A) Partial lipodystrophy at the stage of a lobular panniculitis. Atrophy developed subsequently. (B) Inflammatory changes are usually mild. (H&E)

can develop following the use of protease inhibitor therapy.^{398–402} Clinically evident lipodystrophy usually begins 2–14 months after the commencement of therapy. The changes include loss of fat from the arms, buttocks, thighs, and legs, leading to prominence of veins and muscles, particularly on the legs.⁴⁰³ Loss of the buccal fat pad gives a cachectic appearance.⁴⁰⁰ The accompanying lipohypertrophy includes central obesity, enlargement of the dorsocervical fat pad ('buffalo hump'), and deposition of abdominal fat. Indinavir is the protease inhibitor most often implicated. There has been a recent report of circumferential lipohypertrophy involving the neck, termed 'bullfrog neck', among HIV patients receiving the non-nucleoside reverse transcriptase inhibitor efavirenz.⁴⁰⁴ Resolution of the lipodystrophy usually occurs on discontinuation of the therapy.³⁹⁸ It has been suggested that protease inhibitors bind to proteins that regulate lipid metabolism. Dysregulation of peroxisome function also occurs.⁴⁰⁵

A similar lipodystrophy has been reported with the use of reverse transcriptase inhibitors. It has been suggested that these cases may in some way be related to suppression of HIV replication.⁴⁰¹

Finally, a third group of HIV-related cases appears to exist. Some patients with AIDS develop a facial lipoatrophy; not all have been on protease or reverse transcriptase inhibitor therapy.

Autologous fat grafts for the enhancement of facial contours have met with high patient satisfaction rates.⁴⁰⁶ Poly lactic acid implants are

Figure 17.16 Lipodystrophy (lipoatrophy). Involutional changes are apparent; they include marked atrophy of the fat lobule, small lipocytes, intervening hyaline material, and numerous capillaries. (H&E)

another successful strategy.⁴⁰⁷ The human growth hormone-releasing factor synthetic analog, tesamorelin, given by subcutaneous injection, appears to be helpful in reducing the excess abdominal fat that accompanies HIV-associated lipodystrophy.⁴⁰⁸

Histopathology⁴⁰⁰

The lipoatrophy resembles the non-inflammatory variant of lipodystrophy (discussed previously). There is atrophy of fat, sometimes accompanied by an alteration in the size and shape of adipocytes. The fat cells were reported as having a normal spherical shape in one report.⁴⁰¹ Focal collections of lymphocytes and lipophages are sometimes present, but they are not a prominent feature. A proliferation of small vessels may occur at the interface between the atrophic lobules and the septa, resembling immature (fetal) fat.

Reports of the microscopic findings in the lipohypertrophic areas associated with HIV-related lipodystrophy are difficult to find. However, in insulin-induced lipohypertrophy, adipocytes may be twice as large as those in non-hypertrophic sites (Fig. 17.18), and small lipid droplets can be seen at the periphery of a minority of these hypertrophic cells.⁴⁰⁹ In a report of lipohypertrophy due to subcutaneous

Figure 17.17 Lipedema. (A) Edema and adipocyte degeneration are present. (H&E) (B) Pseudoxanthoma-like changes of septal elastic fibers were present in this particular case. (von Kossa)

injection of pegvisomant, a growth hormone receptor antagonist used in the treatment of acromegaly, the adipocytes were said to be normal in appearance. However, the photomicrograph suggests that these adipocytes may also be enlarged, although confirmation would require a biopsy of uninvolved fat for comparison.⁴¹⁰ The ‘lipomatous’ areas from patients with familial partial lipodystrophy also show enlarged adipocytes compared to those from perilipomatous tissues of both patients and controls.⁴¹¹

GYNOID LIPODYSTROPHY (CELLULITE)

Gynoid lipodystrophy, better known as cellulite, is an alteration of the topography of the skin that occurs mainly in women on the buttocks, thighs, and abdomen.⁴¹² It gives the skin a dimpled (‘orange peel’, ‘quilted’, ‘mattress’) appearance.^{413,414} It is very common in obese patients, although it differs from obesity both structurally and mechanistically.^{412,415} Four grades of clinicopathological severity have been defined.⁴¹²

Figure 17.18 Lipohypertrophy. Adipocytes are approximately twice as large as those in non-hypertrophic sites. This was from a case of insulin-induced lipohypertrophy. (H&E)

The pathogenesis of gynoid lipodystrophy is complex and still being elucidated, but it includes alterations in the composition and the amount of fat in adipocytes, changes in the microcirculation of the subcutis, and hyperpolymerization in the connective tissue of the fat septa.⁴¹² These changes appear to be influenced by hormonal and psychosomatic factors as well as by race, sedentary lifestyle, and an inherent predisposition.⁴¹² Cellulite appears to predispose to earlier skin aging changes.⁴¹⁶ The pathophysiology of cellulite has been reviewed in detail in a recent publication.⁴¹⁷

Histopathology^{412,413}

There is no consensus on the histopathological features of gynoid lipodystrophy, possibly reflecting different stages of the disease process. Furthermore, there appears to be a physiological difference between the dermal–subcutaneous interface in men and women, with a smooth interface in males and a tendency to a ‘lumpy’ appearance in females as a consequence of the protrusion of superficial fat lobules into the dermis.⁴¹³

In early stages, the superficial fat lobules are large. They may be squeezed between straightened fibrous septa, which are of variable thickness. This latter feature becomes more obvious in established cases when lumpy and loose swellings are interposed between thinner areas of the septa; a few myofibroblasts are present. The septa may come to resemble areas of striae distensae (see p. 368) with associated alterations in the elastic tissue that may consist of clumped and increased fibers and other areas with reduced elastic tissue.⁴¹³ Small collections of adipocytes may become encapsulated with fibrous strands.

Vascular changes are variable and may involve the dermis as well. There is often neovascularization, dilatation of vessels, intimal thickening of small arteries, and microaneurysms with hemorrhage.⁴¹²

MEMBRANOUS LIPODYSTROPHY

The term ‘membranous lipodystrophy’ was originally applied to a sudanophilic sclerosing leukoencephalopathy in which cystic degeneration of the marrow of long bones also occurred.⁴¹⁸ The fat showed a characteristic lipomembranous (membranocystic) change (see

later). The term has since been applied to a varied group of panniculitides in which this same lipomembranous change occurs. The term *pseudomembranous fat necrosis* is also used.⁴¹⁹ There are several cases in the literature in which this change has been found as a primary phenomenon in the subcutaneous fat of the skin; it has therefore been proposed that such cases should be designated *primary membranous lipodystrophy* to distinguish them from the cases in which it is merely an incidental histological feature – *secondary membranous lipodystrophy*.^{420–422} Diseases in this latter category include erythema nodosum,^{302,423} morphea profunda,⁴¹⁸ lupus panniculitis, traumatic fat necrosis, insulin lipodystrophy,⁴²⁴ the panniculitis of Behçet's syndrome, encapsulated fat necrosis, and the panniculitis of dermatomyositis.^{419,425} Membranous lipodystrophy also occurs in association with circulatory disturbances, particularly diabetic microangiopathy and venous insufficiency; vasculitis-induced lesions are rare.⁴²⁶ Because lipodermatosclerosis also occurs in a setting of venous insufficiency, it is perhaps not surprising that lipomembranous change is common in lipodermatosclerosis.⁴²⁷

It seems likely that membranous lipodystrophy will eventually be regarded as synonymous with lipomembranous (membranocystic) change – a histological change rather than a disease *sui generis*.

Histopathology^{273,419–421}

Membranous lipodystrophy (pseudomembranous fat necrosis) is characterized by lipomembranous (membranocystic) change. There are cysts of varying size, usually small, lined by amorphous, eosinophilic material having an arabesque architecture (Fig. 17.19). It results from the interaction of residual products of disintegrated fat cells and macrophages.⁴¹⁸ Sometimes the membranes form small pseudopapillae.⁴²⁸ The material is stained by the PAS and Sudan black methods. Between groups of fat cysts, there are dense, thick, fibrous septa. Myospherulosis (see p. 455) has been noted in two cases.^{429,430} In secondary membranous lipodystrophy, changes of the underlying process will, of course, be present as well.

LIPODERMATOSCLEROSIS

Criticisms notwithstanding,⁴³¹ 'lipodermatosclerosis' is still the preferred term for an entity characterized by circumscribed, indurated, often inflammatory plaques on the lower extremities. In a series of 97 patients reviewed at the Mayo Clinic, 84 were women, and the mean age was 62 years.⁴³² Lesions were bilateral in nearly half of the cases. The condition is usually associated with venous insufficiency, arterial ischemia, or previous thrombophlebitis.^{293,433} One case developed during therapy with gemcitabine⁴³⁴ and another as a form of radiation recall dermatitis.⁴³⁵ It may also complicate chronic lymphedema. There may also be mottled hyperpigmentation related to venous stasis.⁴³⁶ Sometimes the clinical appearances mimic a cellulitis. Similar lesions have been reported as *sclerosing panniculitis*⁴³⁷ and *hypodermatitis sclerodermiformis*. So-called 'lipomembranous' (membranocystic) change is frequently seen on histology; thus, this condition has also been regarded as a *membranous lipodystrophy* (discussed previously) or simply called *lipomembranous (membranocystic) fat necrosis*.³⁰²

Lipodermatosclerosis appears to be a consequence of ischemia and venous stasis. Venous insufficiency was thought to be present in a case in a 15-year-old girl.⁴³⁸ There is abnormally low plasma fibrinolytic activity in these patients, as well as low levels of proteins C and S.⁴³⁹ However, fibrinolytic activity is increased in affected tissues, and this is associated with elevated levels of urokinase-type plasminogen activator (uPA).⁴⁴⁰ In addition, there is elevated matrix turnover, although the significance of this finding is uncertain.⁴⁴¹ Sclerosis is also a feature.⁴⁴² There is a significant increase in the number of dermal fibroblasts undergoing proliferation and also an increase in the number of cells

Figure 17.19 (A) Lipomembranous fat necrosis. (B) There is some sclerosis in the wall of the fat cyst that is lined by hyaline eosinophilic material with an arabesque pattern. (H&E)

expressing procollagen type 1 mRNA.⁴⁴³ Ultrasound investigations have shown that the edema fluid in this condition is predominantly in the upper dermis in contrast to the deep dermal location of the fluid in chronic heart failure.⁴⁴⁴ Magnetic resonance imaging (MRI) can be used as a diagnostic tool in this condition.⁴⁴⁵ Because light compression appears to enhance the removal of edema fluid, compression stockings have been used in the treatment of lipodermatosclerosis.⁴⁴⁶ Other therapies used have included stanozolol combined with compression therapy, surgical correction of venous disease, pentoxifylline, and intralesional triamcinolone.⁴⁴⁷

Histopathology

Biopsies are usually obtained in the later stages of the disease when there is septal fibrosis and sclerosis and fatty microcysts with foci of membranocystic change. This consists of amorphous eosinophilic material, sometimes with a crenelated appearance, lining microcysts (Fig. 17.20). This material is PAS positive and stains with Sudan black.⁴²⁰ Microgranules may be present in macrophages. Hemosiderin pigment is often present in the dermis; it may also be in the subcutis. There is fibrosis of the dermis and pericapillary fibrin caps around small vessels in the upper dermis. The fibrous thickening of the lower dermis means that a punch biopsy of an involved area of skin may not include any subcutaneous fat (Fig. 17.21).

Figure 17.20 Lipodermatosclerosis. Striking membranocystic changes are present in the later stage lesion. (H&E)

In early lesions (uncommonly biopsied as the site heals poorly), there is a septal and lobular panniculitis, with lymphocytes being the predominant cell. There is variable fat necrosis; sometimes an entire lobule is infarcted. Blood vessels appear prominent in the septa at all stages. Inflammation is often minimal, although lymphocytes, eosinophils, and plasma cells may be present.⁴⁴⁸ Plasma cells are sometimes quite numerous in lipodermatosclerosis; they express CD79a, CD138, and epithelial membrane antigen, and they are polyclonal when stained for κ and λ light chains.⁴⁴⁹ Short, frayed elastic fibers are seen in subcutaneous septa, and these are sometimes calcified (as demonstrated with the von Kossa stain), producing a resemblance to pseudoxanthoma elasticum.⁴⁴⁸ Calcification can also be seen in the intima and media of blood vessels, in the interstitium, in the walls of pseudocysts, and around adipocytes.⁴⁴⁸

FACTITIAL AND TRAUMATIC PANNICULITIS

The clinical manifestations of self-induced panniculitis or other forms of traumatic panniculitis will depend on the nature and site of the insult. Factitial panniculitis may follow injections of all manner of

Figure 17.21 (A) Lipodermatosclerosis. (B) Fibrous tissue replaces the subcutis. There is mild chronic inflammation at the level of the sweat glands. There is some hemosiderin pigment in the lower dermis. (H&E)

substances – including milk, urine, feces, oils (oleoma), and drugs – into the subcutaneous fat. A case masquerading as pyoderma gangrenosum has been reported.⁴⁵⁰ Sclerosing lipogranuloma (paraffinoma) is a special form of factitial panniculitis resulting from the injection of lipid, often paraffin, into the subcutaneous tissue,⁴⁵¹ particularly in an attempt to produce enlargement of the penis and even the breasts.^{452,453} Other oils and silicones have been involved.^{454–456} The lesion presents as a painful rubbery induration of the involved area. Fistulas and ulceration are common.⁴⁵⁷ Oil cysts developed after the regular subcutaneous injections of interferon- α and interleukin-2 (IL-2) for metastatic melanoma. However, because the injectable solutions are water based, it was postulated that the injection of these cytokines may have led to a focal liponecrosis with resulting fat cysts.⁴⁵⁸ Grease gun granuloma with panniculitis results from the accidental firing of this device, which is used especially by auto mechanics; a verrucous nodule results, often appearing on the dorsum of the hand.⁴⁵⁹

Mesotherapy injections for ‘cellulite’ produced a granulomatous panniculitis with some fat cysts.⁴⁶⁰ Injectable therapeutic agents producing panniculitis have included procaine povidone,⁴⁶¹ meperidine (pethidine),⁴⁶² pentazocine,⁴⁶³ morphine, tetanus antitoxoid, phytonadione,⁴⁶⁴ aurothioglucose,⁴⁶⁵ IL-2,⁴⁶⁶ and bovine collagen.⁴⁶⁷ Phytonadione (vitamin K) injection is responsible for Texier’s disease, in which sclerotic lesions with lilac-colored borders form around the buttocks and thighs, producing a resemblance to a ‘cowboy gunbelt and holster’.⁴⁶⁴ A localized panniculitis has also been reported following the subcutaneous injection of glatiramer acetate in the treatment of multiple sclerosis.^{297,468} Transient reactions and pain are not uncommon complications, but more persistent lesions occur.

Subcutaneous fat necrosis may follow trauma, particularly to the shins. Focal liquefaction of the injured fat often follows, and this is sometimes discharged through a surface wound. Some cases of traumatic fat necrosis have a factitial origin, so there is obvious overlap with factitial panniculitis.⁴⁶⁹ Hypertrichosis has occurred in areas of panniculitis resulting from blunt trauma; local hyperemia or angiogenesis have been suggested as possible triggering factors for the hypertrichosis in those cases.^{470,471}

Histopathology

Although factitial panniculitis usually produces a lobular or mixed panniculitis, other patterns such as a suppurative septal panniculitis can occur (Fig. 17.22).⁴⁵⁰ Foreign body giant cells with foreign material, sometimes doubly refractile, may be present. It is recommended to examine by polarized light any unusual suppurative panniculitis or one with foreign body-type granulomas.

In paraffinomas and oleomas, there is a characteristic Swiss-cheese appearance with disruption of fat cells and their replacement by cystic spaces of variable size, some surrounded by attenuated foreign body giant cells containing lipid vacuoles.^{453,456} There are bands of hyaline fibrous tissue between the fat cysts. The septa contain a scattering of lymphocytes and lipid-containing macrophages and foreign body giant cells. This pattern is referred to as sclerosing lipogranuloma. Grease gun granulomas combine these features with overlying pseudoepitheliomatous hyperplasia (Fig. 17.23).⁴⁵⁹

The reactions that developed following the injection of glatiramer acetate consisted of a mostly lobular panniculitis, with histiocytes and T lymphocytes in the fat lobules, and thickened septa with scattered lymphoid follicles.⁴⁶⁸

An unusual pattern of *transdermal elimination of fat cells* occurs after fat necrosis of various etiologies. The author has seen it follow erythema nodosum, traumatic fat necrosis, and lupus erythematosus panniculitis. Clinically, the lesion may weep over an area of induration. Clusters of degenerated fat cells are seen high in the dermis. Small tissue spaces may represent degenerate fat removed during tissue processing.

Figure 17.22 (A) An unusual case of factitial panniculitis. (B) There is suppuration involving the interlobular septa. The deep fascia contains some doubly refractile foreign material, the nature of which was not ascertained. (H&E)

Figure 17.23 Sclerosing lipogranuloma (grease gun granuloma). (A) This biopsy, from the dorsum of the hand, shows pseudoepitheliomatous hyperplasia. (B) Cystic spaces in the subcutis are surrounded by bands of hyaline fibrous tissue. (H&E)

Cases of traumatic fat necrosis (traumatic panniculitis) coming to biopsy usually show fat cysts of varying size with surrounding fibrosis. The microcysts sometimes show lipomembranous (membranocystic) change. There are often small collections of foam cells, a mild patchy lymphocytic infiltrate, and some hemosiderin. In earlier lesions, there is fat necrosis with cystic spaces and numerous neutrophils in the adjacent fat. A similar appearance follows surgical disruption of the subcutis.⁴⁷² Sometimes collections of fat cells, often necrotic, can be seen within the dermis, apparently in the process of being eliminated through a break in the epidermis.

Differential diagnosis

In sclerosing lipogranuloma and related lipogranulomas, the large vacuoles found in the dermis and subcutis are distinctive, but if necessary special stains for exogenous lipids can be performed on frozen sections. Radiographs are sometimes used in distinguishing lipogranulomas from silicone granulomas because only the latter are radio-opaque. Infrared spectrophotometry identified mineral oil in nonprocessed tissue. Panniculitis due to injectable substances can be distinguished from primary forms of panniculitis by the presence in the former of significant dermal changes or of foreign material that can be identified, at times, by polarization microscopy. Cases with acute inflammation and necrosis may resemble infection-induced panniculitis, and in fact infection may accompany injection panniculitis. Special stains and cultures for organisms are useful in problem cases. Sclerosing forms of traumatic/factitial panniculitis (e.g., due to phytonadione or pentazocine) may resemble morphea but would not be expected to manifest as a primarily septal panniculitis. Organizing hematomas with deposition of iron pigments are often found in panniculitis due to blunt trauma.

POSTIRRADIATION PSEUDOSCLERODERMATOUS PANNICULITIS

The term pseudosclerodermatous panniculitis was used by Winkelmann and colleagues in 1993 to describe four cases of women with breast cancers who received megavoltage radiotherapy.⁴⁷³ Further cases have since been described.⁴⁷⁴ All patients developed progressive induration of the subcutaneous tissues in the irradiated area. In one series, the interval between radiotherapy and the development of the induration varied from 4 to 8 months.⁴⁷⁴

Histopathology

The main findings were confined to the subcutaneous tissue and consisted of thickened, sclerotic septa combined with a lobular panniculitis characterized by centrally located adipocyte necrosis, lipophagic granulomas, lipophages, and scattered lymphocytes and plasma cells.⁴⁷⁴ In chronic radiodermatitis, findings include papillary dermal sclerosis, vasodilatation and endothelial swelling with hyaline sclerosis of vessel walls, and stellate fibroblasts among collagen bundles.⁴⁷⁵

ENCAPSULATED FAT NECROSIS

Encapsulated fat necrosis is the preferred designation for the small mobile nodules that may develop in the subcutis; they often follow trauma.^{476,477} These lesions have also been called 'mobile encapsulated lipoma' and 'nodular-cystic fat necrosis'.⁴⁷⁸

The lesions, which are usually solitary, are whitish-yellow in color and measure 3–20 mm in diameter.⁴⁷⁶ An unusually large case, measuring 18 cm in longest diameter, has been reported in an elderly female with morbid obesity.⁴⁷⁹ Encapsulated fat necrosis has also been reported in a patient with sarcoidosis.⁴⁸⁰

Figure 17.24 Encapsulated fat necrosis. There is a hyaline capsule with central fat necrosis and cystic change. (H&E)

Histopathology

The lesions are composed of lobules of necrotic fat surrounded by a thin fibrous capsule that is usually hyaline (Fig. 17.24). Lipomembranous change (discussed previously) is often present.^{421,479,481} Small collections of lipophages and very focal inflammatory changes are sometimes seen, particularly near the capsule. Dystrophic calcification may be a late complication.

INFECTIVE PANNICULITIS

Various infections and infestations may result in a lobular or mixed lobular and septal panniculitis.^{4,482} These include candidiasis,⁴²⁰ cryptococcosis, mycetoma, actinomycosis, nocardiosis, chromomycosis, sporotrichosis, and histoplasmosis;^{483,484} infections with *Borrelia burgdorferi*,⁴⁸⁵ *Mycobacterium marinum*,⁴⁸⁶ *M. chelonae*,⁴⁸⁷ *M. ulcerans*, *M. fortuitum*, *M. tuberculosis*,⁴⁸⁸ *M. leprae* (erythema nodosum leprosum; see p. 662), *M. avium-intracellulare*,⁴⁸⁹ *Neisseria meningitidis*, and other bacteria;^{482,490} bites of ticks⁴⁹¹ and of the brown recluse spider (*Loxosceles reclusa*);⁵⁵ and metazoal infestations (myiasis, cysticercosis, sparganosis, and infestations by some other helminths). Most cases of infection-induced panniculitis occur in patients who are immunosuppressed.⁴⁸² Two subcutaneous nodules developed in a patient with chronic myeloid leukemia who contracted Q fever.⁴⁹² 'New' forms of infective panniculitis have been reported in association with leishmaniasis, of both cutaneous^{493,494} and visceral⁴⁹⁵ types, brucellosis,⁴⁹⁶ and schistosomiasis.⁴⁹⁷

Histopathology⁴⁸²

The presence of a lobular or mixed lobular and septal panniculitis in which there is a heavy infiltrate of neutrophils,⁴⁸⁸ often with extension into the dermis, should raise the suspicion of an infective etiology (Fig. 17.25). Microcysts lined by neutrophils are often found to harbor microorganisms; this is particularly the case in mycobacterial panniculitis (Fig. 17.26). Hemorrhage and necrosis are often present. In a case of neutrophilic lobular panniculitis due to acanthamebiasis, trophozoites measuring 20–30 μm in diameter were present.⁴⁹⁸

The patient who had Q fever presented with a granulomatous lobular panniculitis with a characteristic 'fibrin ring' or 'doughnut' appearance with fibrin and inflammatory cells arranged around a central clear space. Similar changes have been described in the liver

Figure 17.25 *Mycobacterium ulcerans*. The presence of a widespread suppurative panniculitis, as shown here, warrants exclusion of an infective etiology. Numerous acid-fast bacilli were present. (H&E)

Figure 17.26 Infective panniculitis due to atypical mycobacteria. (A) Within the subcutis are microcysts lined by neutrophils. (H&E) (B) Numerous mycobacterial organisms are seen with special staining. (Ziehl-Neelsen)

and bone marrow in this disease.⁴⁹² Specific microscopic findings associated with various infectious agents have been recently reviewed.⁴⁹⁹

Differential diagnosis

The presence of fluctuant or ulcerating lesions can suggest pancreatic panniculitis, traumatic panniculitis, or α_1 -antitrypsin deficiency panniculitis. Clinical and laboratory data usually permit distinction among these entities. Infection-induced panniculitis with predominantly septal involvement can be confused with erythema nodosum, whereas those examples with medium-vessel vasculitis can resemble erythema induratum. Special stains for organisms and tissue cultures are obviously keys to the diagnosis of infective panniculitis. In one study, special stains were positive for organisms in 14 of 15 cases.⁴⁸² A series of cases of mucormycosis-induced panniculitis featured ghost-like adipocytes with eosinophilic cytoplasm and granular basophilic calcium deposition – features resembling pancreatic panniculitis – and intracellular crystalline deposits, resembling the urate deposits of gouty panniculitis but in formalin-fixed tissue sections.⁵⁰⁰ All cases featured the broad, nonseptate hyphae characteristic of mucormycosis, staining with PAS, GMS, Grocott, and anti-BCG antibody methods. In all cases, serum amylase, lipase, and uric acid levels were within normal limits. The explanation for these microscopic changes may lie in characteristics of fungi of the Mucoraceae family, which are known to produce both extracellular lipases and oxalic acid; the latter in turn could react with calcium to form calcium oxalate crystals in tissues.⁵⁰⁰

NEUTROPHILIC PANNICULITIS

Neutrophilic panniculitis presents with multiple, often painful, subcutaneous nodules on the legs, arms, and trunk. Between 10 and 20 nodules may be present.⁵⁰¹ The lesions are erythematous and deep on palpation. They tend to last approximately 15 days.⁵⁰¹ Although an infective cause should always be considered in the presence of a neutrophilic panniculitis, other etiologies do exist.^{502,503} In the early stages of many of the panniculitides, neutrophilic infiltration occurs. Examples include erythema nodosum, Behçet's disease, pancreatic panniculitis, and factitial panniculitis. Other causes of neutrophilic panniculitis include rheumatoid arthritis,⁵⁰² including the juvenile form,⁵⁰⁴ Sweet's syndrome,^{505,506} and Crohn's disease.⁵⁰⁷ Myelodysplastic syndromes⁵⁰⁸ seem to be significantly associated with a neutrophilic panniculitis. A neutrophilic lobular panniculitis has been reported in a patient with acute promyelocytic leukemia treated with all-*trans*-retinoic acid.⁵⁰⁹ Neutrophilic panniculitis has been associated with treatment of myelodysplastic syndrome with azacitidine⁵¹⁰ and, on a number of occasions, with vemurafenib therapy of metastatic melanoma.^{511–513} One case of neutrophilic panniculitis responded to the IL-1 antagonist anakinra.⁵¹⁴

Magro *et al.* introduced the term '**acute infectious id panniculitis/panniculitic bacterid**' for a neutrophilic lobular panniculitis triggered by nontuberculous infectious stimuli.⁵¹⁵ The disease may be self-limited and respond to antibiotics.⁵¹⁵

Histopathology

There is a heavy infiltrate of neutrophils in the subcutaneous fat, predominantly in the fat lobules, but sometimes showing mild septal spillover. There is no vasculitis and no significant dermal involvement. An infective etiology should be excluded.

In subcutaneous histiocytoid Sweet's syndrome, the infiltrate consists of many immature neutrophils with a histiocytoid appearance.⁵¹⁶

In panniculitic bacterid (discussed previously), there is a neutrophilic panniculitis with subcutaneous microabscesses. Extravascular granulomatous infiltrates and a necrotizing vasculitis are often present.⁵¹⁴

Figure 17.27 Eosinophilic panniculitis. There is an almost pure infiltrate of eosinophils throughout the lobules of fat. A helminth was found nearby. (H&E)

EOSINOPHILIC PANNICULITIS

The term 'eosinophilic panniculitis' has been applied to several different disease entities.⁵¹⁷ It has been used for a mixed lobular and septal panniculitis with numerous eosinophils and flame figures and features resembling those seen in the dermis in Wells' syndrome (see p. 1132).⁵¹⁸ In these cases, the panniculitis was thought to have followed inflammation or infection of the upper aerodigestive tract.^{518,519} The term has been used for a panniculitis with numerous eosinophils in the infiltrate.⁸⁴ As such, it is not a specific entity but, rather, a nonspecific pattern seen in a diverse range of systemic diseases, including erythema nodosum, vasculitis, parasitic infestation (**Fig. 17.27**), malignant lymphoma, atopy,⁵²⁰ AIDS,⁵²¹ and narcotic dependency with injection granulomas.⁶⁴ An eosinophilic panniculitis is usually seen in an exaggerated arthropod bite reaction, but the accompanying dermal inflammation usually allows a specific diagnosis to be made.⁵²² An eosinophilic panniculitis (septal or mixed septal and lobular) has been reported following the infusion of apomorphine for Parkinson's disease.¹² Other causes include intramuscular benzathine penicillin injection,⁵²³ allergen immunotherapy,⁵²⁴ hypersensitivity to calcium heparin,⁵²⁵ as part of an eruption of insect bite-like lesions in a patient with chronic lymphocytic leukemia,⁵²⁶ Kimura's disease,⁵²⁷ and following a molten aluminum burn.⁵²⁸ It has also been related to trauma.⁵²² The term has also been used for a nodular migratory panniculitis that may accompany infestations with the larva of the nematode *Gnathostoma spinigerum* (deep larva migrans).^{529,530} In this variety, eosinophils make up 95% of the infiltrate. Finally, an eosinophilic panniculitis may rarely occur with other parasitic infestations, such as *Fasciola hepatica*.⁴⁴¹ Unlike *Gnathostoma*-induced cases, no parasites are present in the panniculitis.

Eosinophilic panniculitis is not a clinical diagnosis but, rather, a tissue reaction pattern with several etiologies.⁹

CALCIPHYLAXIS

Calciphylaxis presents as painful livedo reticularis and tender erythematous plaques or nodules on the buttocks, abdomen, breasts, and the extremities. Most cases are associated with end-stage renal failure with secondary hyperparathyroidism.^{531,532} The mortality rate is 60–80%. An indolent, more benign form ('protracted' calciphylaxis)

Figure 17.28 Dermatomyositis panniculitis. In this case, there is a mixed septal-lobular panniculitis, composed mainly of lymphocytes. (H&E)

has been seen.⁴²⁷ Calciophylaxis is discussed in more detail with the cutaneous calcifications in Chapter 14 (p. 425).

Histopathology

In addition to the calcification in small blood vessels in the dermis and subcutis, there is lobular fat necrosis, intralobular calcification, and an inflammatory infiltrate of neutrophils, lymphocytes, and foamy macrophages.⁸

MISCELLANEOUS LESIONS

The miscellaneous causes of a panniculitis, discussed here, are listed in Table 17.3. A focal nonspecific panniculitis may be found in some cases of dermatomyositis, particularly in relation to underlying calcified deposits.^{533,534} In a few cases, tender, indurated plaques and nodules develop; they have the histological features of a lobular panniculitis (Fig. 17.28).^{535,536}

Panniculitis with urate crystal deposition and necrosis of fat has been reported as the only cutaneous manifestation of gout.^{537–540} Urate panniculitis also developed in a child who had received multiple organ transplants.⁵⁴¹

In the severe form of hydroa vacciniforme (see p. 623), a lobular or septal panniculitis and/or vasculitis are often present.⁵⁴²

A hemorrhagic panniculitis has followed atheromatous embolization of vessels of the skin.⁵⁴³

A mixed lobular and septal panniculitis was present in erythematous nodules that developed at the sites of previous chemotherapy injections (chemotherapy recall reaction).⁵⁴⁴

Noncaseating granulomas may be found rarely in the subcutaneous tissue in Crohn’s disease.⁵⁴⁵ A neutrophilic lobular panniculitis with few granulomas has also been reported in Crohn’s disease.⁵⁰⁷

A lobular panniculitis with no particular distinguishing features has been reported in a patient with Niemann–Pick disease.⁵⁴⁶

The panniculitis found in approximately 5% of patients undergoing jejunio-ileal bypass for morbid obesity has been described as erythema nodosum-like⁵⁴⁷ complicated by lobular fat necrosis and as Weber–Christian-like.¹⁷⁷ Published photomicrographs suggest a lobular panniculitis with some resemblance to erythema induratum–nodular vasculitis. A mixed septal and lobular panniculitis is a rare complication of the blind loop syndrome.⁵⁴⁸

Other rare causes of a panniculitis include malignancies,^{549,550} particularly lymphomas.^{4,551,552} Sometimes a florid granulomatous pannicu-

Table 17.3 Miscellaneous causes of lobular panniculitis
Atheromatous embolism
Behçet’s disease
Blind loop syndrome
Chemotherapy recall reaction
Crohn’s disease
Dermatomyositis
Drugs (bromides, cocaine injection, granulocyte colony-stimulating factor, imatinib, iodides, phenytoin, tramadol, trastuzumab)
Granuloma annulare
Histiocytic panniculitis
Hydroa vacciniforme (septal also)
Infections (see infective panniculitis)
Jejuno-ileal bypass
Lymphomas
Niemann–Pick disease
Nutritional abnormalities/low-calorie diets
Oxalosis
Sjögren’s syndrome
Sweet’s syndrome
Urate/gouty panniculitis

litis accompanies the lymphomatous infiltrate; this may mask the correct diagnosis of lymphoma.^{553,554} A lobular panniculitis is common in angiocentric immunoproliferative lesions such as angiocentric T-cell lymphoma (see p. 1192).⁵⁵⁵ A lobular panniculitis with variable numbers of plasma cells has been reported in Sjögren’s syndrome.^{556,557} Sometimes the panniculitis is granulomatous.⁵⁵⁸ The erythema nodosum-like lesions in Behçet’s disease may have either a septal or a lobular panniculitis on histopathological examination.⁸⁸ Drugs such as phenytoin,⁵⁵ trastuzumab,⁵⁵⁹ imatinib,⁵⁶⁰ iodides and bromides, and tramadol⁵⁶¹ and low-calorie diets and nutritional abnormalities⁵⁶² may produce a panniculitis. A necrotizing panniculitis, secondary to vascular thrombosis, may follow the use of recombinant human granulocytic colony-stimulating factor⁵⁶³ or the injection of cocaine.⁵⁶⁴ Granuloma annulare may also involve the subcutis. Panniculitis ossificans has been associated with forms of trauma⁵⁶⁵ and was recently reported in an individual whose only apparent relevant history was performing excessive push-ups.⁵⁶⁶ A mixed septal-lobular panniculitis has accompanied allergic contact dermatitis, probably resulting from tattoos containing potassium dichromate and cobalt chloride.⁵⁶⁷ Cases that defy an etiological classification are sometimes seen. One such case was reported as ‘suppressor-cytotoxic T-lymphocyte panniculitis’. The patient was febrile and had a lobular panniculitis with many CD8⁺ lymphocytes in the infiltrate.⁵⁶⁸ Another case had an unusual histiocytic infiltrate in the dermis and subcutis (both septal and lobular) admixed with inflammatory cells.⁵⁶⁹ The cells were positive for S100 and CD68, and they were negative for CD1a.⁵⁶⁹

PANNICULITIS SECONDARY TO LARGE VESSEL VASCULITIS

A localized area of panniculitis is almost invariable in the immediate vicinity of an inflamed large artery or vein, as it courses through the subcutaneous fat. There is no lobular panniculitis of contiguous lobules as is seen in erythema induratum–nodular vasculitis.

Figure 17.29 Superficial migratory thrombophlebitis involving a small vein in the subcutis. Sometimes an elastic tissue stain is needed to distinguish between small arteries and arterialized veins in biopsies from the lower leg. The pattern of smooth muscle is more reliable. An artery usually has a continuous wreath of concentric smooth muscle, whereas a vein has bundled muscle fibers with intermixed collagen. (H&E)

CUTANEOUS POLYARTERITIS NODOSA

There is a benign cutaneous form of polyarteritis nodosa that is distinct from the systemic form. It presents with painful subcutaneous nodules in crops, mainly on the lower limbs. There may be other associated cutaneous features. It is considered further in Chapter 8 (p. 243). In microscopic polyangiitis (see p. 242), there may be a septal panniculitis.

SUPERFICIAL MIGRATORY THROMBOPHLEBITIS

Superficial migratory thrombophlebitis presents as erythematous subcutaneous nodules or cord-like areas of induration, usually on the lower limbs. It may be associated with other conditions, such as carcinoma of the pancreas, Behçet's disease, and Buerger's disease. The panniculitis is limited to the area immediately adjacent to the involved vessel (**Fig. 17.29**). This entity is considered further in Chapter 8 (p. 245).

INTRODUCTION

This chapter covers a diverse group of diseases that have in common a disturbance in metabolism or bodily function. Many of these conditions have a genetic basis, most of which have been elucidated in the past three decades.

Three major disease categories are considered in this chapter:

- Vitamin and dietary disturbances
- Lysosomal storage diseases
- Miscellaneous metabolic and systemic diseases.

The various diseases included in these categories show a wide range of histopathological changes. They are discussed in turn.

VITAMIN AND DIETARY DISTURBANCES

The skin and mucous membranes may be affected in various vitamin deficiency states. Usually multiple vitamins are involved because the most common cause of deficiency is a nutritional disturbance. Nutritional deficiencies may result from alcoholism,¹ digestive tract disease (including cystic fibrosis,² resections, and bypass surgery), dietary fads, and anorexia nervosa.³⁻⁵ The cutaneous manifestations of vitamin⁶ and nutritional⁷ deficiencies were reviewed some years ago. Cutaneous manifestations are particularly seen in vitamin C deficiency (scurvy), vitamin A deficiency (phrynodema), and niacin (nicotinic acid) deficiency. These deficiencies are discussed further here. Vitamin D has little to do with cutaneous disease, but potential insufficiency of this vitamin as a consequence of sun protection methods is discussed briefly later.

Kwashiorkor, which results from protein malnutrition, is characterized by xerosis, patches of hypopigmentation, skin peeling, peripheral edema, and thin hair shafts.⁷⁻¹² It may follow a protein-poor diet.^{13,14} Deficiency of essential fatty acids, seen in some patients receiving parenteral nutrition, results in alopecia, xerosis, and intertriginous erosions.⁷

Riboflavin and pyridoxine deficiency both lead to glossitis, angular stomatitis, cheilosis, and a condition resembling seborrheic dermatitis.^{7,15} In riboflavin deficiency, there may be a scrotal dermatitis, whereas in pyridoxine deficiency there may be pellagra-like features.⁷

Carotenemia, secondary to excessive dietary ingestion of foods containing β -carotene, is sometimes seen in young children fed commercial baby foods.¹⁶ It presents with orange-tinted skin. It is not the only cause of xanthoderma.¹⁷ Carotenemia can also be seen in adults with dietary fads.¹⁸

SCURVY

Scurvy results from a deficiency of vitamin C (ascorbic acid) which is a water-soluble vitamin necessary for proline hydroxylation in the formation of collagen.^{6,19,20} Vitamin C also plays a role in normal hair growth. Loss of the integrity of collagen leads to inadequate support for small vessels, resulting in hemorrhage from minor trauma.²¹ This is characteristically perifollicular in distribution, but spontaneous petechiae and ecchymoses may also develop.^{6,22} Other features include follicular hyperkeratosis, abnormal hair growth with the formation of corkscrew hairs,²³ bleeding gums, and poor wound healing.^{6,24} Woody edema of the lower limbs with some surface scaling may be the only manifestation.²¹ Spontaneous hemarthrosis should suggest the diagnosis of scurvy, particularly in the absence of abnormalities in coagulation studies.²⁵ In one patient, the manifestations of scurvy were limited to a previously injured extremity.²⁶ Scurvy may be seen in alcoholics and

Figure 18.1 Scurvy. The patient ate one brand of cookie as her only food. There is red cell extravasation, mild follicular hyperkeratosis, and perifollicular fibrosis. (H&E)

those with dietary fads and inadequacies²⁷⁻³⁰ and, accordingly, associated deficiencies of other factors may contribute to the appearance of the cutaneous lesions.³¹ It has also been seen in liver transplant recipients.³² Dietary intake of vitamin C is essential, because it is not stored in the body.³³ Rarely, there is no explanation for the deficiency.³⁴

Histopathology

A characteristic feature is the presence of extravasated erythrocytes around vessels in the upper dermis (**Fig. 18.1**). This is often in a perifollicular distribution initially. Hemosiderin, a legacy of earlier hemorrhages, is sometimes found. There may also be follicular hyperkeratosis with coiled, fragmented, corkscrew-like hairs buried in the keratotic follicular material (**Fig. 18.2**).²⁴ Ulceration of the skin is sometimes seen. A 'gelatinous' change in the bone marrow can be seen on core biopsy, resulting from accumulation of acid mucopolysaccharides in areas of hypocellularity with lipoatrophy; this change can also be found on magnetic resonance imaging due to resulting altered signal characteristics.³⁵ Gelatinous changes are not specific to scurvy; they can also be seen in conditions such as renal insufficiency, tuberculosis, and HIV infection.³⁵

Electron microscopy

Affected skin may show alterations in fibroblasts, with defective collagen formation.³⁶ There may also be alterations in the endothelial cells of vessels and their junctions.³⁶

VITAMIN A DEFICIENCY

Vitamin A is a fat-soluble vitamin; its active form is retinol. Deficiencies are rare and usually related to malabsorption states.^{6,37-39} A recent example accompanied bowel-associated dermatosis–arthritis syndrome due to a biliopancreatic diversion procedure for obesity.⁴⁰ The skin becomes dry and scaly with follicular keratotic papules (phrynodema).⁴¹ Ocular changes include night blindness,^{42,43} physical findings include keratitis and Bitot spots, which are irregular focal deposits of keratin in the conjunctiva.⁴⁴

Histopathology

Sections show hyperkeratosis and prominent keratotic follicular plugging.⁴² Sweat glands may be atrophic; in severe cases, they show squamous metaplasia.⁴¹

Figure 18.2 Scurvy. There is a cross-sectional profile of a distorted hair shaft within the follicular lumen. Perifollicular hemorrhage and mild perivascular inflammation are present. (H&E)

HYPERVITAMINOSIS A

Hypervitaminosis A is usually a result of self-administration of excess amounts of the vitamin.⁴⁵⁻⁴⁷ Acute symptoms include vomiting, diarrhea, and desquamation of skin. In the chronic form of vitamin A toxicity, there is dry skin, cheilitis, and patchy alopecia. Histological changes are nonspecific.

VITAMIN D

The principal physiological function of vitamin D is to maintain calcium homeostasis. By maintaining the calcium $\times$ phosphate product, vitamin D plays a role in bone metabolism. In the past, vitamin D deficiency was associated with rickets in children and osteomalacia in adults. In recent years, there has been debate about whether sun avoidance, with a goal of skin cancer prevention, may compromise vitamin D sufficiency.⁴⁸ An excellent review of this topic was published in 2006.⁴⁸ The following conclusions were reached by this review: (1) many of the potential benefits of maintaining normal serum 25-OH vitamin D levels (recently revised upwards) are possible but largely unproven, and (2) maintaining these levels is best achieved by increasing the daily intake of vitamin

D by the use of fortified foods and/or dietary supplementation and not by more sun exposure.⁴⁸

VITAMIN K DEFICIENCY

Vitamin K is a fat-soluble vitamin that is necessary for the hepatic synthesis or secretion of various coagulation factors.⁶ A deficiency may result from liver disease and from malabsorption; in infants, it may be associated with diarrhea. Purpura is a common manifestation of vitamin K deficiency.

The parenteral injection of vitamin K may rarely give rise to an erythematous plaque at the site of injection, apparently due to a delayed hypersensitivity reaction.⁴⁹ A late sclerodermatous reaction is a rare complication (see p. 360).

VITAMIN B₁₂ DEFICIENCY

Vitamin B₁₂ deficiency may be associated with poikilodermatous pigmentation. This clinical pattern results from basal pigmentation and some melanin incontinence. A recent report detailed a case of vitamin B₁₂ deficiency resulting from recreational nitric oxide abuse, manifested in part by macular hyperpigmented patches on the trunk.⁵⁰ When nitrous oxide is cleaved into free oxygen and nitrogen, the result is the rapid oxidation and inactivation of vitamin B₁₂.⁵⁰ Although the mechanism of this hyperpigmentation is unclear, it has been proposed that vitamin B₁₂ deficiency results in decreased intracellular levels of the tyrosinase-inhibiting reduced glutathione, which in turn promotes melanin production by epidermal melanocytes.⁵¹ The nuclei of keratinocytes were reported to be larger than normal in one patient.⁵¹

PELLAGRA

Pellagra is a multisystem nutritional disorder caused by inadequate amounts of niacin (nicotinic acid) in the tissues.^{52,53} This may result from a primary dietary deficiency,⁵⁴⁻⁵⁹ chronic alcoholism,⁶⁰ malabsorption, certain chemotherapeutic agents such as isoniazid,^{61,62} 6-mercaptopurine, 5-fluorouracil,⁶³ azathioprine,⁶⁴ 'alternative remedies',⁶⁵ anticonvulsants,^{66,67} and chloramphenicol. A pellagroid dermatitis occurred in a 20-year-old patient receiving anti-epileptic therapy (valproic acid and ethosuximide) and a ketogenic diet, following discontinuation of vitamin supplementation.⁶⁸ Pellagra may also result from abnormalities of tryptophan metabolism.⁶ In this latter category is the carcinoid syndrome, in which tumor cells divert tryptophan metabolism toward serotonin and away from nicotinic acid, and Hartnup disease, in which there is a congenital defect in tryptophan absorption and transfer⁶ (see p. 571). Nicotinamide, the active amide of niacin, is being investigated for its property of inhibiting photocarcinogenesis and photoimmunosuppression.¹³

Pellagra is traditionally remembered as the 'disease of the four Ds': dermatitis, diarrhea, dementia, and, if untreated, death.⁶⁹ The skin lesions commence as a burning erythema in sun-exposed areas, particularly the dorsum of the hands and the face and neck.⁷⁰ Blistering may occur. This is followed by intense hyperpigmentation with sharp margination and areas of epithelial desquamation.⁶ The 'tanning' occurs more slowly than in typical sunburn.⁷¹ There may also be glossitis, angular cheilitis, and vulvitis.⁶⁹

Histopathology⁵²

The findings are not diagnostic. They include hyperkeratosis, parakeratosis, epidermal atrophy with pallor of the upper epidermis, and hyperpigmentation of the basal layer (Fig. 18.3).^{6,72} There is usually a

Figure 18.3 (A) Pellagra. (B) There is partial necrosis and hemorrhage involving the superficial epidermis with underlying psoriasiform acanthosis. (H&E)

Figure 18.4 Vacuolated fibroblasts in the skin in a lysosomal storage disease. The type of vacuole present is not diagnostic of a particular condition. (×5000)

mild, superficial dermal infiltrate of lymphocytes. Vasodilatation and extravasated erythrocytes are often seen.⁷³ Mild keratotic follicular plugging is sometimes seen in biopsies from the face.⁶¹ Bullae may be either intraepidermal or subepidermal.⁷⁰ Hyperplasia of the sebaceous glands with follicular dilatation and plugging may occur.^{52,74}

Similar histopathological changes are seen in Hartnup disease (see p. 571).

LYSOSOMAL STORAGE DISEASES

Lysosomal storage diseases are a group of individually rare, but collectively numerous, inherited disorders of intracellular metabolism.⁷⁵ More than 45 different disorders are recognized, many of which are neurodegenerative in nature. Fifteen of these disorders account for 75% of lysosomal storage diseases.⁷⁵ They are a specific subset of the inborn errors of metabolism: they are characterized by a deficiency in a specific lysosomal hydrolase or of a protein essential for the normal function of lysosomes.⁷⁶ As a consequence of this deficiency, there is accumulation of the specific substrate in various organs of the body. The distribution of this stored material corresponds to the site where degradation of the substrate usually occurs. Lysosomes are particularly plentiful in macrophages and other cells of the mononuclear phagocyte system: organs rich in these cells, such as the liver and spleen, are frequently enlarged. In one subgroup of lysosomal storage diseases, the sphingolipidoses, there is an accumulation of certain glycolipids or phospholipids in various organs, particularly the brain.

The lysosomal storage diseases can be diagnosed by assaying for the specific enzyme thought to be deficient in serum, leukocytes or cultured fibroblasts,⁷⁶ or the protein amount.⁷⁵ In many of these diseases, inclusions can be found on ultrastructural examination of the skin (**Fig. 18.4**). The inclusions are sometimes sufficiently distinctive to be diagnostic of a particular disease, although in many instances they are not. Accordingly, ultrastructural examination of the skin in the diagnosis of

the lysosomal storage diseases is usually no more than a useful adjunct to enzyme assay.⁷⁷ A fluorescent analogue of lactosylceramide has shown promise as a screening test for the sphingolipidoses and some other lysosomal storage diseases. It accumulates in the lysosomes of cultured fibroblasts from affected patients.⁷⁸

With ultrastructural studies of the skin, care must be taken to avoid overdiagnosis.⁷⁷ Many cells in the skin may, at times, contain a few vacuoles, fat globules, or other inclusions.⁷⁷ These must not be misinterpreted as indicating a lysosomal storage disease.

The lysosomal storage diseases, which have a prevalence of 1 in 7700 in the general Australian population, can be divided into several categories on the basis of the biochemical nature of the accumulated substrate.^{79,80}

- Sphingolipidoses
- Oligosaccharidoses
- Mucopolidoses
- Mucopolysaccharidoses
- Others.

SPHINGOLIPIDOSES

The sphingolipidoses are a heterogeneous group of lysosomal storage diseases that result from a variety of enzyme deficiencies affecting different levels in the metabolism of complex lipids. Certain glycolipids or phospholipids accumulate in various tissues of the body, particularly the brain.⁸¹ Cutaneous changes are present in many of the sphingolipidoses.⁷⁷

G_{M2}-gangliosidoses

The G_{M2}-gangliosidoses are a subgroup of sphingolipidoses in which there is an accumulation of the ganglioside G_{M2} as a result of a defect in some aspect of the hexosaminidase system.^{76,82} The most common clinical variant is Tay–Sachs disease (OMIM 272800), in which there is progressive psychomotor deterioration and blindness. It is due to a mutation in the gene encoding the α subunit of the hexosaminidase A enzyme (*HEXA*) on chromosome 15q23–q24. In Sandhoff's disease (OMIM 268800), which is phenotypically similar, the gangliosides are deposited in nearly all cells of the body, in contrast to Tay–Sachs disease, in which deposits do not occur outside the nervous system.^{77,83} In Sandhoff's disease, the mutation involves the β subunit of hexosaminidase (*HEXB*), on chromosome 5q13.⁸⁴

Histopathology

Cytoplasmic inclusions can be seen in a number of cells in osmified, semithin, Epon-embedded sections in Sandhoff's disease.⁸⁵

Electron microscopy

Membrane-bound inclusions can be found in endothelial cells, smooth muscle cells, pericytes, Schwann cells, and eccrine secretory cells. There are lamellar and vacuolar structures and 'zebra bodies' (vacuoles with transverse membranes). In Tay–Sachs disease, lesions are confined to nerve axons, which may be distended by residual bodies, a change also seen in Sandhoff's disease.⁷⁷

Inclusion bodies are also found in cultured fibroblasts in Sandhoff's disease, but they are quite sparse in Tay–Sachs disease.⁸⁶

G_{M1}-gangliosidoses

G_{M1}-gangliosidosis (OMIM 230500) is an autosomal recessive lysosomal storage disease caused by a mutation in the gene encoding β -galactosidase-1 (*GLB1*). There are two major clinical variants of G_{M1}-gangliosidosis, of which Norman–Landing disease (pseudo-Hurler's syndrome) is the more severe.⁸² This infantile form (type I)

is characterized clinically by a gargoye-like appearance, psychomotor regression, blindness, hirsutism, hepatosplenomegaly, and deformities of the hands and feet.^{77,87} As in G_{M2}-gangliosidosis, a 'cherry-red spot' is often present. Extensive dermal melanocytosis has been reported in several patients with G_{M1}-gangliosidosis.⁸⁸

The diagnosis can be made by measuring β -galactosidase activity in leukocytes or cultured skin fibroblasts.⁷⁶

Histopathology

Vacuolation of fibroblasts, endothelial cells, and eccrine secretory cells is sometimes discernible in sections stained with hematoxylin and eosin (H&E).⁸⁷

In patients with associated dermal melanocytosis, lesional skin shows elongated melanocytes with fine melanin pigment.⁸⁸

Electron microscopy

There is vacuolation of fibroblasts, endothelial cells, smooth muscle cells, and sweat gland epithelium. Schwann cells are less severely affected.⁷⁷ The vacuoles are empty or contain fine fibrillar or flocculent material.⁸⁹ Inclusions are also found in cultured fibroblasts.⁸⁶

Gaucher's disease

Gaucher's disease is the most prevalent sphingolipidosis, with a frequency of 1 in 50,000–100,000 live births in white populations and 1 in 850 in Ashkenazi Jews.⁹⁰ Gaucher's disease is categorized phenotypically into three main subtypes. All forms are caused by mutations in the gene encoding glucocerebrosidase (*GBA*) on chromosome 1q21; more than 200 mutations are known.^{91–94} Type I Gaucher's disease (OMIM 230800) is the most common form; it lacks central nervous system involvement, as occurs in the other types.⁹⁵

In Gaucher's disease, glucocerebroside accumulates in the cells of the mononuclear macrophage system (reticuloendothelial system).^{96–98} This condition is not discussed further because skin biopsies have consistently been negative, with no evidence of stored lipid in sweat ducts, fibroblasts, or cutaneous nerves.^{77,89}

Fabry's disease

Fabry's disease (OMIM 301500) is an uncommon X-linked recessive disorder of glycosphingolipid metabolism in which there is a deficiency of the lysosomal hydrolase, α -galactosidase A (formerly called ceramide trihexosidase).^{99–101} The gene maps to Xq22. This leads to the accumulation of ceramide trihexoside in various tissues of the body, particularly the vascular and supporting elements.

The disease usually presents in late adolescence with recurrent fevers associated with pain in the fingers and toes and intermittent edema.^{99,102–104} Characteristic whorled opacities are usually present in the cornea (cornea verticillata).^{99,100} Cerebrovascular and cardiovascular disturbances are common, and progressive renal damage leading to renal failure in the fourth and fifth decades of life is almost invariable.^{102,105} Atopic eczema is not increased.¹⁰⁶ Heterozygous females are often asymptomatic, but they may show evidence of the disease to different degrees.^{107–110} Therefore, they are more than 'carriers' of the gene.

The diagnosis of Fabry's disease can be made on the urine lipid profile and by the reduced α -galactosidase A activity in peripheral blood leukocytes.¹¹⁰

The cutaneous lesions (angiokeratoma corporis diffusum) are multiple, deep red telangiectases clustered on the lower part of the trunk, buttocks, thighs, scrotum, and the shaft of the penis (see p. 1080).⁹⁹ Angiokeratomas were present in 66% of males and 36% of females registered on the Fabry Outcome Survey, a multicenter European database of 714 patients (at the time of the review).¹¹¹ Most sites can

be involved, although the face and scalp are usually spared. Petechial lesions are rarely present.¹¹² Increased vascular endothelial growth factor-A (VEGF-A) levels have been found in patients with Fabry's disease compared to controls, which may reflect a response to the vessel injury associated with this disorder.¹¹³ Cutaneous lesions are occasionally absent.¹⁰⁰ Multiple leg ulcers have also been described.¹¹⁴ Other cutaneous findings include lymphedema, anhidrosis or hypohidrosis, and pseudo-acromegalic facies.¹¹⁵

Note that angiokeratomas are not confined to Fabry's disease. They may also occur in sialidosis, fucosidosis, adult-onset G_{M1} -gangliosidosis, aspartylglycosaminuria, β -mannosidosis, α -N-acetylgalactosaminidase deficiency, galactosialidosis, and in an idiopathic form.

There can be clinical benefits of enzyme replacement therapy in earlier stages of the disease, particularly with regard to heart and kidney function, pain, and quality of life. However, response is variable among subgroups of patients,¹¹⁶ and further study is needed to assess the long-term benefits of this therapy.¹¹⁷ The effect of enzyme replacement therapy on the vasculopathy in Fabry's disease appears to be minimal.¹¹⁸ Because this therapy is expensive,¹¹⁹ it is important that a correct diagnosis, with biochemical confirmation, is made prior to therapy.^{120,121}

Histopathology

There are large and small thin-walled vessels in the upper dermis (see p. 1080). The overlying epidermis is often thinned, with variable overlying hyperkeratosis. There are often acanthotic or elongated portions of rete ridge at the periphery of the lesions.¹²² The vessels are angiectatic and not a new growth. Fibrin thrombi are sometimes present in the lumen.¹²³ There may be patchy vacuolization of the media of vessels in the deep dermis in both affected and normal skin. If frozen sections are examined, doubly refractile material may be seen in the vicinity of these vacuoles.⁹⁹ The material will also stain with Sudan black and the PAS stain (Fig. 18.5).¹²⁴ The peroxidase-labeled lectins of *Ricinus communis* and *Bandeiraea simplicifolia* have been found to be strongly reactive with the material on frozen sections.¹²⁵ Fine PAS-positive granules are sometimes seen in the sweat glands.¹²³

In semithin sections, fine intracytoplasmic granules can be seen in eccrine glands, vessel walls, and fibroblasts in the dermis.

Electron microscopy^{124,126}

Diagnostic intracytoplasmic inclusions having a lamellar structure can be found in endothelial cells, pericytes, fibroblasts, myoepithelial cells

of sweat glands, and macrophages. Involvement of eccrine secretory cells is uncommon,¹⁰⁰ and that of Schwann cells is rare.⁸⁵ The inclusions, which are sometimes membrane bound, may also be found in heterozygotes in skin biopsies¹²⁴ and cultured fibroblasts.⁸⁶

Metachromatic leukodystrophy

Metachromatic leukodystrophy (OMIM 250100) results from a deficiency in the activity of arylsulfatase A and the accumulation of metachromatic sulfatides in the nervous system and certain other organs.^{76,82} Clinically, there is progressive psychomotor retardation. The gene maps to chromosome 22q13.31-qter.

Histopathology

Vacuolated cells are sometimes seen in the endoneurium of cutaneous nerves. Brown metachromatic material can be seen in these nerves after cresyl violet staining of frozen sections.¹²⁷

Electron microscopy¹²⁷

The Schwann cells of myelinated nerves contain so-called 'tuff-stone' or 'herring bone' inclusions that are membrane bound.^{77,85,128} Macrophages containing myelin breakdown products are found within the nerves. Inclusions with a concentric lamellar structure have been reported in cultured fibroblasts.⁸⁶

Krabbe's disease

Krabbe's disease (globoid cell leukodystrophy; OMIM 245200) is an autosomal recessive disease that results from a mutation in the galactosylceramidase gene on chromosome 14q31. As a consequence, there is a deficiency of the lysosomal enzyme galactocerebrosidase.^{76,129} There are progressive neurological symptoms, beginning usually in childhood, as a consequence of the apoptotic death of oligodendrocytes and Schwann cells resulting from the accumulation of psychosine.¹²⁹ Its incidence in the United States is 1 in 100,000 live births.¹²⁹

Histopathology

Globoid cells with PAS-positive cytoplasm are found in the central nervous system, particularly in the white matter.¹³⁰ Cutaneous nerves appear normal on light microscopy.

Electron microscopy

Tubular and crystalloid inclusions have been reported in Schwann cells in cutaneous nerves,^{85,130} but not consistently.⁸⁹ Cultured fibroblasts do not contain specific inclusions.⁸⁶

Disseminated lipogranulomatosis (Farber's disease)

Disseminated lipogranulomatosis (Farber's disease; OMIM 228000) is a rare, autosomal recessive disorder of lipid metabolism in which there is a deficiency of acid ceramidase leading to an accumulation of ceramide and its degradation products.^{131,132} The defect maps to chromosome 8p22-p21.3. Several mutations have been described. The main clinical features usually appear at the age of 2–4 months and comprise progressive arthropathy, the development of subcutaneous, often periarticular nodules, hoarseness, irritability, and pulmonary failure.¹³³ The disease is progressive, with death usually occurring in early childhood.¹³³

The diagnosis can be made by demonstrating a deficiency in ceramidase in cultured fibroblasts or in white blood cells.¹³⁴

Histopathology¹³⁵

There is extensive fibrosis of the reticular dermis and subcutis with collagen bundles of variable thickness traversing the nodules

Figure 18.5 Fabry's disease. This frozen section shows dilated deep dermal vessels containing deposits of glycosphingolipid. (Sudan black)

in various directions. Within the fibrotic areas are many histiocytes with distended, somewhat foamy cytoplasm.^{132,136} Some cells are multinucleate. A few lymphocytes and plasma cells are often present. Histochemical stains have given variable results, depending on whether paraffin or frozen sections have been used. The oil red O stain and Baker's reaction for phospholipid may be positive.¹³⁵

Electron microscopy^{134,136}

There are characteristic curvilinear bodies (Farber bodies) within the cytoplasm of fibroblasts and occasionally of endothelial cells. They are also found within phagosomes of histiocytes at various stages of degradation. Banana-like bodies can be found within Schwann cells. 'Zebra bodies' (vacuoles with transverse membranes) may be seen in some endothelial cells. They represent gangliosides and may be found in other storage diseases.¹³⁴

Niemann–Pick disease

Niemann–Pick disease is a rare autosomal recessive disorder in which sphingomyelin accumulates in many organs due to a deficiency of sphingomyelinase.¹³⁷ It is characterized by progressive neurodegeneration. It is a heterogeneous entity with more than one enzyme defect involved.^{138–141} Several types have been described: type A (OMIM 257200), the predominant type, is due to a mutation in the sphingomyelin phosphodiesterase-1 gene (*SMPD1*) on chromosome 11p15.4–p15.1; type B (OMIM 607616), which is allelic to type A, has visceral involvement but no neurological disease (types E and F are included here); type C1 (OMIM 257220) and type D are caused by mutations in the *NPC1* gene on chromosome 18q11–q12; and type C2 (OMIM 607625) is due to a mutation in the *NPC2* gene at 14q24.3.¹⁴² The *NPC* genes appear to regulate intracellular trafficking of cholesterol and other lipids. The course is unremitting, and death usually occurs in early childhood.

Cutaneous lesions have been reported in a small number of cases and include diffuse tan brown hyperpigmentation, indurated brown plaques,¹⁴³ facial papules,¹⁴⁴ xanthomas,¹³⁷ and juvenile xanthogranulomas.^{145,146} A nodular panniculitis has been described in a patient with type C disease.¹⁴⁷ A small number of cases have abnormalities in skin barrier function as a consequence of a marked reduction in sphingomyelin-derived ceramide.¹⁴⁸

Histopathology

It is now thought that the lesions reported clinically as juvenile xanthogranulomas in Niemann–Pick disease are xanthomas associated with the basic phospholipid abnormality.^{139,145} This view is based on the presence of cytoplasmic zebra bodies on electron microscopy of one case.¹⁴⁵ In the cutaneous lesions described, there are large numbers of foamy histiocytes in the dermis admixed with a few lymphocytes. The foamy cells may have a pale brownish appearance in sections stained with H&E.¹⁴⁴ The vacuoles may impart a mulberry appearance. The cytoplasmic lipids stain with oil red O and Sudan black;¹³⁷ they are metachromatic with toluidine blue.¹⁴⁴ Scattered multinucleate cells are present. Using a lysenin-affinity staining technique, Thurberg *et al.* detected sphingomyelin storage in dermal fibroblasts, macrophages, endothelial and vascular smooth muscle cells, perineurium, and Schwann cells – findings confirmed by electron microscopic analysis.¹⁴⁹

Electron microscopy

Cultured fibroblasts from patients with Niemann–Pick disease show characteristic membrane-bound myelin-like inclusions.⁸⁶ 'Washed-out' inclusions with a lamellar structure have been reported in endothelial cells and Schwann cells in the skin.⁸⁹

OLIGOSACCHARIDOSES

The oligosaccharidoses (glycoproteinoses) are characterized by excess urinary excretion of oligosaccharides as a consequence of a deficiency in one of the lysosomal enzymes responsible for the degradation of the oligosaccharide portion of glycoproteins.⁷⁶ The four disorders included in this subgroup of lysosomal storage diseases are sialidosis, fucosidosis, mannosidosis, and aspartyl-glycosaminuria. The cutaneous manifestations of this last condition have not been studied extensively, and it is not considered further.

Sialidosis

Sialidosis (mucopolipidosis I, neuraminidase deficiency; OMIM 256550) results from a deficiency of neuraminidase (sialidase),¹⁵⁰ caused by mutations in the *NEU1* gene on chromosome 6p21.3. Clinical features include coarse facies, ataxia, myoclonus, and a cherry-red spot in the macula.¹⁵⁰

Galactosialidosis (OMIM 256540) is a slowly progressive neurodegenerative disease, with similar phenotypic features, that results from the combined deficiency of neuraminidase (sialidase) and β -galactosidase.^{151,152} Several different mutations have been described in the *PPGB* gene that maps to 20q13.1. There is the lack of a 32-kDa 'protective protein' that is crucial for the biological activity of these two enzymes. Angiokeratomas have been reported in patients with this combined deficiency state.^{152,153}

Histopathology

Skin biopsies in sialidosis appear normal in sections stained with H&E. In the combined deficiency, angiokeratomas may be present (see p. 1080): the endothelium of these vessels is sometimes vacuolated.¹⁵²

Electron microscopy

Cultured fibroblasts from patients with sialidosis contain cytoplasmic vacuoles similar to those observed in various mucopolysaccharidoses and in mannosidosis.¹⁵⁴

In *galactosialidosis*, vacuoles are seen in the endothelium of vessels and also in fibroblasts, sweat gland epithelium, and the Schwann cells of nonmyelinated nerves. The vacuoles are mostly empty, but some contain floccular material.¹⁵² Lamellar inclusions also occur. Vacuolar and lamellar inclusions are present in cultured fibroblasts.¹⁵⁴

Fucosidosis

Fucosidosis (OMIM 230000) is a rare autosomal recessive disorder in which a deficiency of the lysosomal enzyme α -L-fucosidase leads to the accumulation of fucose-containing glycolipids and other substances in various tissues.^{155,156} The gene *FUCA1*, on chromosome 1p34, encodes this enzyme; more than 20 different mutations have been described.¹⁵⁷ Approximately 100 cases have been reported worldwide.¹⁵⁷ There is early onset of psychomotor retardation and other neurological signs. Three clinical variants have been reported, but only type 3 is associated with cutaneous lesions.¹⁵⁸ These lesions are indistinguishable from the angiokeratomas seen in Fabry's disease (see p. 563).^{157,159,160} Hypohidrosis, increased palmoplantar vascularity, and widespread telangiectasia may also be present.¹⁶¹

Bone marrow transplantation is reported to be an effective treatment.¹⁵⁷ Enzyme replacement therapy or gene therapy is unlikely to become available in the near future.¹⁵⁷

Histopathology

The angiokeratomas are composed of dilated vessels in the papillary dermis (see p. 1080). The endothelial cells of these and other dermal

vessels are vacuolated and somewhat swollen, leading to narrowing of the lumen of some small dermal vessels.¹⁵⁹ The eccrine secretory coils are lined by uniformly vacuolated cells.¹⁵⁹

Electron microscopy^{155,161,162}

There are membrane-bound vacuoles containing fine granular material in endothelial cells, fibroblasts, melanocytes, histiocytes, eccrine glands, and occasional pericytes. Lamellated bodies representing complex lipids are present in myoepithelial cells of sweat glands and in Schwann cells.¹⁵⁹ Both types of cytosome are sparsely distributed in epidermal keratinocytes.^{159,163} Smooth muscle cells are uninvolved.¹⁵⁹

Mannosidosis

Two types of mannosidosis have been identified: α -mannosidosis (OMIM 248500), caused by a mutation in the gene *MAN2B1*, found at 19cen-q12, encoding the lysosomal enzyme α -mannosidase; and β -mannosidosis (OMIM 248510), an extremely rare condition, due to a mutation in the *MANBA* gene, encoding β -mannosidase, on chromosome 4q22-q25.^{164,165}

In α -mannosidosis, the deficiency of the lysosomal enzyme α -mannosidase leads to an accumulation of mannose-containing oligosaccharides in various tissues of the body, including the nervous system.¹⁶⁶ Patients have a gargoyle-like facies and mental retardation. The condition runs a relatively benign clinical course.

In β -mannosidosis, there are facial dysmorphism, skeletal deformities, respiratory and skin infections, angiokeratomas, hepatosplenomegaly, and neurological abnormalities.^{164,165}

Histopathology

Biopsies from hyperplastic gingiva in α -mannosidosis have shown vacuolated histiocytes in the lamina propria containing PAS-positive material.¹⁶⁶ The angiokeratomas found in β -mannosidosis resemble those seen in other conditions.

Electron microscopy

Membrane-bound vacuoles containing fine granular material are present in many different cells of the body, including cultures of skin fibroblasts, in both forms of the disease.^{154,164}

MUCOLIPIDOSES

The mucolipidoses are a group of lysosomal storage diseases that have clinical and biochemical features of both the mucopolysaccharidoses and the sphingolipidoses.⁷⁶ Glycolipids and glycosaminoglycans accumulate in the tissues. Type I mucolipidosis has been reclassified as sialidosis (discussed previously), whereas type IV (OMIM 252650), which results from a mutation in the gene (*MCOLN1*) encoding mucolipin-1, is an autosomal recessive neurodegenerative disease. The most widely investigated of the mucolipidoses is I-cell disease (mucopolidosis II; OMIM 252500), so named because of the numerous inclusions seen in fibroblasts cultured from patients with the disease.⁷⁶ Type III mucolipidosis (OMIM 252600) is regarded as a milder form of I-cell disease. They are allelic, but other subtypes of type III involving other genes have been recorded.¹⁶⁷

I-cell disease

I-cell disease (mucopolidosis II) is caused by a mutation in the *GNPTAB* gene.¹⁶⁸ I-cell disease (OMIM 252500) is an autosomal recessive neurodegenerative disorder, characterized by a marked intracellular deficiency of a number of lysosomal hydrolases and by a significant elevation of these enzymes in plasma.¹⁶⁹ It is caused by a deficiency of uridine-diphosphate-*N*-acetylglucosamine 1-phosphotransferase, the

enzyme that phosphorylates mannose residues of glycoproteins to allow their delivery to lysosomes.^{170,171} The gene maps to chromosome 12q23.3, although there has been conflicting assignment to 4q21-q23.

Clinically, there are short stature, facial dysmorphism, progressive mental and motor retardation, and bony deformities.^{172,173} The skin is generally pale and smooth.¹⁷² A 'blueberry muffin' rash has been reported in a recent case.¹⁷⁴

Histopathology

The dermis may have an increased number of oval or spindle-shaped cells, some with clear or foamy cytoplasm.¹⁷² The cytoplasmic inclusions are PAS positive and metachromatic; they stain with oil red O in frozen sections.

Electron microscopy

There are membrane-bound vacuoles in the cytoplasm of various cells, including fibroblasts, pericytes, Schwann cells, secretory cells of the eccrine glands, and endothelial cells.^{77,173} The vacuoles may contain a few dark rings. The inclusions in endothelial cells are more electron dense and multivesicular.¹⁷² Cultured fibroblasts contain electron-dense inclusions.¹⁵⁴

In *mucopolidosis IV*, there are small dense lipid and zebra bodies in addition to the vacuoles.⁷⁷

OTHER LYSOSOMAL STORAGE DISEASES

Included in this group are glycogenosis type II, the neuronal ceroid-lipofuscinoses, a heterogeneous group of neurodegenerative disorders, and cystinosis.

The mucopolysaccharidoses are another major group of lysosomal storage diseases. They are considered with the mucinoses in Chapter 13 (see p. 422).

Trimethylaminuria (OMIM 602079), also known as fish-odor syndrome, is a rare metabolic disorder characterized by a body malodor similar to that of decaying fish.¹⁷⁵ The condition is caused by mutations in the flavin-containing monooxygenase 3 (*FMO3*) gene, on chromosome 1q23-q25, resulting in the accumulation of trimethylamine.¹⁷⁵

Glycogenosis (type II)

Glycogenosis (type II), also known as glycogen storage disease II (OMIM 232300), is an autosomal recessive disease caused by mutations in the gene (*GAA*) encoding acid α -1,4-glucosidase (acid maltase), which maps to chromosome 17q25.2-q25.3.⁷⁶ In the classic infantile form (Pompe's disease), children are hypotonic with enlarged hearts.

Histopathology

Glycogen is present in many cells in the skin and is best seen in biopsies fixed in Carnoy's solution and stained by the PAS method.

Electron microscopy

Clustered glycogen granules, enclosed within a limiting membrane, are found in many types of cells in the skin, including the arrector pili muscles.^{77,85,89}

Neuronal ceroid-lipofuscinoses

The neuronal ceroid-lipofuscinoses are a heterogeneous group of progressive neurodegenerative disorders characterized by the accumulation of autofluorescent ceroid or lipofuscin-like substances in various organs, especially the nervous system.¹⁷⁶⁻¹⁷⁸ Types 1-10 have

been identified, all with different genetic abnormalities and gene localizations. They were originally identified by the age of onset, but this has been discontinued since the genetic abnormalities have been identified. Type 1 (OMIM 256730) was the original infantile form. Abnormal peroxidation of fatty acids may be the metabolic basis.¹⁷⁶

Histopathology

Affected cells contain yellow-brown pigment that is autofluorescent.^{85,176} In late infantile neuronal ceroid-lipofuscinosis (CLN2), eosinophilic intracytoplasmic inclusion bodies were identified in eccrine sweat glands; these were highlighted with PAS staining and corresponded to curvilinear inclusions found on electron microscopy.¹⁷⁹

Electron microscopy^{177,180}

Characteristic membrane-bound inclusions with a curvilinear or fingerprint¹⁸¹ pattern have been reported in eccrine secretory cells, endothelial cells, smooth muscle cells, and macrophages.⁷⁷ They are particularly prominent in endothelial cells.⁸⁹ Inclusions have not been found consistently in fibroblasts and Schwann cells.¹⁸² In one report, only granular osmiophilic deposits were found; there were no curvilinear or fingerprint inclusions in the cytoplasm of several cell types in the dermis.¹⁸³

Cystinosis

Cystinosis (OMIM 219800) is a lysosomal storage disease resulting from an error in the transmembrane transport of the amino acid cystine. It results from a mutation in the gene encoding cystinosin on chromosome 17p13. There is storage of cystine in multiple organs of the body, particularly the kidney, pancreas, cornea, central nervous system, and muscle. Skin and hair pigmentation is reduced, possibly resulting from impaired pigment formation in melanosomes. Cystine deposits in macrophages in the skin (Fig. 18.6). Near-infrared *in vivo* reflectance confocal microscopy shows bright particles within the papillary dermis in all tested patients, corresponding to cystine crystal deposits in dermal fibroblasts seen with electron microscopy.¹⁸⁴

NECROLYTIC ERYTHEMAS

The necrolytic erythemas are a group of cutaneous diseases of diverse metabolic origin that share certain histopathological features. In addition to the major conditions of acrodermatitis enteropathica, glucagonoma syndrome, necrolytic acral erythema, and Hartnup disease, several other rare conditions are discussed very briefly because of some shared features with these prototype conditions.

ACRODERMATITIS ENTEROPATHICA

Acrodermatitis enteropathica (OMIM 201100) is a rare autosomal recessive defect in the zinc transporter protein ZIP4, encoded by the *SLC39A4* (*hZIP4*) gene on chromosome 8q24.3.^{185–187} Additional zinc transporters may be involved in this condition.^{186,188} It has an estimated incidence of 1 per 500,000 children.¹⁸⁸ It usually presents in infancy, at the time of weaning, with the triad of alopecia, diarrhea, and dermatitis.^{189,190} The cutaneous lesions are periorificial and acral in distribution. There is a crusted eczematous eruption that is sometimes vesiculobullous or pustular.¹⁹¹ Intercurrent infection with bacteria and yeasts, possibly related to impaired chemotaxis,¹⁹² complicates the clinical picture.^{191,193} Other features include photophobia, nail dystrophy, hair shaft abnormalities,¹⁹⁴ short stature, progressive depigmentation,¹⁹⁵ stomatitis, and emotional disturbances. There are uncommon,

Figure 18.6 Cystinosis. (A) The brownish crystals are in macrophages. There is perivascular accentuation. (H&E) (B) The crystals are doubly refractile under polarized light. (Slides by courtesy of Dr. Mark Wilsher, DHM, Sydney)

mild forms of the disease,¹⁹⁶ some of which may not be diagnosed until adult life.^{197,198}

Transient symptomatic zinc deficiency may also develop in advanced cancer¹⁹⁹ and in premature infants on artificial feeding,²⁰⁰ and rarely in breast-fed infants, both premature^{186,187,201–205} and full-term,^{206,207} associated with low or marginal levels of zinc in maternal milk.²⁰⁸ Premature infants are more vulnerable to the development of zinc deficiency than are full-term infants because they have low body stores of zinc and a poor capability to absorb zinc from the gut, despite their high zinc requirements.^{209,210} Sometimes serum zinc levels may be misleadingly normal.²¹¹ Other rare causes of an acrodermatitis enteropathica-like eruption have included parenteral nutrition without zinc supplementation,^{212–214} malnutrition,²¹⁵ Crohn's disease,²¹⁶ intestinal bypass procedures,²¹⁷ gastrectomy,²¹⁸ advanced alcoholic cirrhosis,²¹⁹ the nephrotic syndrome,²²⁰ low dietary zinc in adults,²²¹ AIDS,²²² Hartnup disease,²²³ arginine deficiency,²²⁴ ornithine transcarbamylase deficiency (OMIM 311250),^{224,225} an X-linked disease on chromosome Xp21.1, isoleucine deficiency,²²⁶ anorexia nervosa,^{227,228} and cystic fibrosis.^{229–231}

The abnormality in acrodermatitis enteropathica, referred to previously, involves a novel zinc transporter protein belonging to the ZIP (zinc/iron-regulated transporter-like protein) family.¹⁸⁵ Acrodermatitis enteropathica is responsive to zinc therapy;^{232,233} it needs to be life-long.²³⁴ Several different factors may be implicated in transient symptomatic zinc deficiency. These include diminished tissue stores of zinc in premature infants; the decreased bioavailability of zinc in cow's milk compared to human breast milk; and the rare, idiopathic occurrence of low zinc levels in breast milk, despite normal serum levels.²⁰¹

A periorificial dermatitis resembling acrodermatitis enteropathica may occur in the rare aminoacidopathies, **methylmalonic** (OMIM 251000) and **propionic acidemia** (OMIM 606054).^{235–237} An ichthyosis vulgaris-like rash has also been reported in methylmalonic acidemia.²³⁸ The histopathological changes have been variable.

Selenium deficiency, an essential trace element like zinc, may produce a cardiomyopathy and cutaneous changes similar to zinc deficiency.²³⁹ It may follow parenteral nutrition of long duration.²³⁹

Biotin deficiency can also mimic zinc deficiency clinically.²⁴⁰ It can result from acquired deficiencies (e.g., from the consumption of raw egg whites) or from an inborn error in metabolism, such as biotinidase or multiple carboxylase deficiency.^{241,242} Holocarboxylase synthetase deficiency (OMIM 253270) is a rare autosomal recessive disorder of the biotin metabolism that presents at birth with an erythrodermic eruption of the eyebrows and scalp. It may also present as an ichthyosis.²⁴³ The gene, *HLCS*, is on chromosome 21q22.1.

Necrolytic erythema of the skin was seen in a patient with the exceedingly rare deficiency in **glutamine synthetase** (OMIM 610015), encoded by the *GS* (*GLUL*) gene on 1q31.²⁴⁴ It is involved in ammonia detoxification. Glutamine is largely absent from serum, urine, and cerebrospinal fluid.²⁴⁴

An **amicrobial pustulosis of the flexures and scalp** has been reported in association with various autoimmune diseases.²⁴⁵ It is mentioned here because of its response to zinc supplementation. Another recently recognized aseptic condition has been called **aseptic abscesses**. Visceral organs are involved. The lesions respond to corticosteroids but not antibiotics.²⁴⁶ Approximately two-thirds of affected patients have inflammatory bowel disease.²⁴⁶

Histopathology^{208,247}

The histological changes, which vary with the age of the lesion, are similar to those seen in the necrolytic migratory erythema of the glucagonoma syndrome (see below). In early lesions, there is confluent parakeratosis overlying a normal basket-weave stratum corneum.²⁴⁷ The granular layer is absent, and there is mild spongiosis and acanthosis. There is increasing pallor of the cells in the upper layers of the epidermis and variable psoriasiform epidermal hyperplasia.²⁴⁸ Subcorneal or intraepidermal clefts may develop, but established vesiculobullous lesions are intraepidermal in location and result from cytoplasmic vacuolar change with massive ballooning and reticular change producing cytolysis of keratinocytes.^{249–251} Confluent necrosis leads to enlargement of the vesicles. Sometimes there is necrosis of the upper epidermis, but this was not encountered in one detailed study.²⁵²

In late lesions, there is confluent parakeratosis overlying psoriasiform epidermal hyperplasia, but there is no significant epidermal pallor (Fig. 18.7). Less common findings include apoptotic cells (Fig. 18.8),²⁵³ a few acantholytic cells in vesiculobullous lesions,²⁵⁴ and neutrophils within the epidermis. Secondary infection may complicate the picture.

Blood vessels in the papillary dermis are often dilated, and there is a mild perivascular infiltrate of chronic inflammatory cells.

Pallor of the epidermal cells is also seen in the exceedingly rare **deficiency of the M-subunit of lactate dehydrogenase** (OMIM 150000), reported from Japan and mapped to 11p15.4,^{255,256} a similar disorder has been reported from Europe as 'annually recurring acroerythema'.²⁵⁷

Figure 18.7 (A) Acrodermatitis enteropathica. (B) This late lesion is characterized by confluent parakeratosis overlying an acanthotic epidermis. **(C)** In this example, parakeratosis overlies more prominent psoriasiform hyperplasia. Neutrophils are present in the scale crust at the surface, and a few cells with pale-vacuolated cytoplasm are seen beneath the layer of parakeratosis. (H&E)

Figure 18.8 Acrodermatitis enteropathica. This lesion contains numerous apoptotic cells. (H&E)

Electron microscopy

Findings include lipid droplets and multiple cytoplasmic vacuoles in keratinocytes in the upper dermis.^{212,247,258} Desmosomes may be diminished, associated often with widening of the intercellular space.²⁴⁷

GLUCAGONOMA SYNDROME

The clinical features of the rare glucagonoma syndrome include a distinctive cutaneous eruption (necrolytic migratory erythema), glossitis, stomatitis, diabetic type of glucose intolerance, scotoma, brittle nails,²⁵⁹ anemia, weight loss, venous thrombosis, elevated glucagon levels, and decreased plasma amino acids.^{260–263} A glucagon-secreting islet cell tumor of the pancreas is usually present and is malignant in the majority of cases.^{260,264–267} However, necrolytic migratory erythema has also accompanied glucagon cell adenomatosis.²⁶⁸ The syndrome has also been reported in association with a jejunal adenocarcinoma,²⁶⁹ cholangiocarcinoma,²⁷⁰ in pancreatic insufficiency,²⁷¹ in association with a neuroendocrine tumor producing predominantly insulin,²⁷² in advanced cirrhosis of the liver,^{273,274} in association with villous atrophy of the small intestine,²⁷¹ in malnutrition,²⁷⁵ after intravenous glucagon for hypoglycemia resulting from an insulin-like tumor product,²⁷⁶ and in a patient with elevated glucagon levels but no detectable tumor.²⁷⁷ Impairment of hepatic function has been present in many of the cases of necrolytic migratory erythema without a glucagonoma.^{278–280} Zinc deficiency is sometimes present as well in patients with cirrhosis of the liver,^{280,281} particularly if alcohol related, and combined with malnutrition.²⁸²

The cutaneous lesions, called *necrolytic migratory erythema* because of their similarities to both toxic epidermal necrolysis and annular erythema, are manifest by waves of extending annular or circinate erythema and superficial epidermal necrosis with shedding of the skin leading to flaccid bullae and crusted erosions.²⁸³ There is usually complete resolution of involved areas within 10–14 days.^{284,285} The lesions primarily affect the trunk, groin, perineum, thighs, and buttocks, but the legs, perioral skin,²⁸⁵ and sites of minor trauma may also be involved. Cutaneous lesions are not invariably present in the syndrome. Rarely, they are its only manifestation.^{286,287} Necrolytic migratory erythema has been reported in two patients with opiate dependency. In one case, the rash settled on withdrawal of methadone, only to return on

Figure 18.9 Glucagonoma syndrome. This is an established lesion with a thick zone of pale, vacuolated keratinocytes in the upper epidermis. (H&E)

recommencing methadone.²⁸⁸ It has also been reported in a patient with cystic fibrosis.²⁸⁹

The pathogenesis of the skin lesions is uncertain, but their histological similarities to those seen in other deficiency states, such as pellagra and acrodermatitis enteropathica, and their disappearance with intravenous administration of supplemental amino acids suggest that profound amino acid deficiency induced by the catabolic effects of hyperglucagonemia may be important.^{285,290} Elevated levels of arachidonic acid, an inflammatory mediator, have been found in affected skin.²⁹¹

Lanreotide, an analogue of somatostatin but with a much longer half-life, has been used to treat the glucagonoma syndrome. It does not appear to suppress tumor growth.²⁹² Liver transplantation was used to treat a patient with metastatic glucagonoma.²⁹³

Histopathology²⁹⁴

Several histological patterns may be seen in necrolytic migratory erythema, depending on the stage of evolution of the lesion that is biopsied (**Fig. 18.9**). The most distinctive pattern is the presence of pale, vacuolated keratinocytes in the upper epidermis, leading to focal or

Figure 18.10 (A) Glucagonoma syndrome with psoriasiform hyperplasia. (B) Vacuolated cells are quite conspicuous in the upper layers of the epidermis. (H&E)

confluent necrosis (**Fig. 18.10**).²⁷⁷ This process has been termed ‘necrolysis’.²⁸⁴ Subcorneal or intraepidermal clefts may result; acantholytic cells are rarely found in these clefts.²⁹⁵ Subcorneal pustules are sometimes found adjacent to the areas of necrosis, but they may also be the only manifestation of disease in the biopsy specimen.²⁹⁴ Diffuse neutrophilic infiltration of the epidermis may accompany this pattern (**Fig. 18.11**).²⁹⁶

The least common histological pattern is psoriasiform hyperplasia of the epidermis with overlying confluent parakeratosis and vascular dilatation with some angioplasia in the papillary dermis (**Fig. 18.12**).^{277,297}

In all biopsies, there is usually a mild to moderate perivascular infiltrate of lymphocytes in the upper dermis. Sometimes there are occasional neutrophils as well, particularly if subcorneal pustules are present.

Uncommon histological findings include a suppurative folliculitis, the presence of concomitant candidosis,²⁹⁸ suprabasal acantholysis,²⁹⁹ and scattered dyskeratotic cells in the upper epidermis.³⁰⁰ In one series of 13 patients, the biopsy findings were regarded as suggestive or characteristic of necrolytic migratory erythema in only 8 patients.³⁰¹ The author has seen similar cases, in which several biopsies were performed, but only one showed diagnostic features.

Electron microscopy

In one study, there was widening of the intercellular spaces in the upper epidermis and a reduction in the number of desmosomes.³⁰² The

Figure 18.11 Glucagonoma syndrome. A pustular lesion is present. (H&E)

Figure 18.12 Glucagonoma syndrome. Confluent parakeratosis overlies an epidermis in which there is mild psoriasiform hyperplasia. (H&E)

cytoplasm of affected cells showed vacuolar degeneration with lysis or absence of organelles.³⁰² Scattered dyskeratotic cells were noted.

NECROLYTIC ACRAL ERYTHEMA

Necrolytic acral erythema, first described in 1996, belongs to the family of necrolytic erythemas.³⁰³ This variant is unique in its acral location and its strong association with hepatitis C.^{304–307} However, the prevalence of necrolytic acral erythema among patients with chronic hepatitis C infection was very low in one study – 1.7% among 300 studied patients.³⁰⁸ Clinically, there are eroded erythematous to violaceous patches and tender, flaccid blisters and erosions with hyperkeratotic plaques in older lesions. There is a predilection for the lower limbs. It appears that leukocytoclastic vasculitis (another complication of hepatitis C infection) and necrolytic acral erythema do not develop simultaneously in the same patient. A study by El-Darouti *et al.* showed that high levels of hepatitis C viremia favor the development of leukocytoclastic vasculitis but not necrolytic acral erythema; there also appears to be no correlation between the hepatitis C genotype and the development of one of these disorders.³⁰⁹ The condition responds to treatment with interferon- α and oral zinc, although zinc levels were normal in all the earlier reports.^{304,310} Zinc deficiency has been reported in rare patients with this condition.^{311–313} Furthermore, a recent study confirmed decreased zinc levels in serum, lesional skin and also perilesional skin in patients with necrolytic acral erythema.³¹⁴ Several possible mechanisms for decreased serum zinc levels in this disorder have been suggested, including increased levels of lipopolysaccharide and subsequent cytokine-directed redistribution of zinc and also zinc's role as a cofactor in metalloproteins that regulate the replication of the hepatitis C RNA genome.³¹⁴ Combination therapy with interferon, ribavirin, and hyperalimentation has also been used with success.³¹⁵

Histopathology

The lesions resemble acrodermatitis enteropathica and necrolytic migratory erythema with hyperkeratosis, parakeratosis, superficial pallor of the epidermis, focal necrosis, and spongiosis. There is a superficial mixed inflammatory cell infiltrate in the dermis.³⁰⁴

A histologically similar process has been reported in two patients with anorexia nervosa, following nutritional infusions.³¹⁶ Clinically, the lesions were linear and striae-like.^{316,317}

HARTNUP DISEASE

Hartnup disease (OMIM 234500), named after the first family to be described with this condition,³¹⁸ results from defective intestinal absorption of tryptophan and impaired renal tubular reabsorption of neutral amino acids.³¹⁹ It is caused by mutations in the solute carrier family 6, member 19 (SLC6A 19) gene on chromosome 5p15.³²⁰ There is a photosensitive, pellagra-like skin rash, cerebellar ataxia, mental disturbances, aminoaciduria, and indicanuria.³²¹ Symptoms commence in childhood; there is often some improvement in later life. Other genetic defects of tryptophan metabolism, resulting in some symptoms in common with Hartnup disease, have been described.³²² An acrodermatitis enteropathica-like eruption has also been reported in a child with Hartnup disease²²³ – the reason for its inclusion here.

Histopathology

The changes in the skin are similar to those seen in pellagra (see p. 561).

MISCELLANEOUS METABOLIC AND SYSTEMIC DISEASES

As the heading suggests, this section deals with a heterogeneous group of disorders with variable clinical and histopathological manifestations. The various cutaneous manifestations of **celiac disease** are considered in other sections. They include xerosis,³²³ dermatitis herpetiformis, alopecia areata, chronic urticaria, vasculitis, Sjögren's syndrome, lupus erythematosus, and linear IgA dermatosis.³²⁴

PROLIDASE DEFICIENCY

Prolidase deficiency (peptidase D; OMIM 170100) is an exceedingly rare, autosomal recessive, inborn error of metabolism in which recalcitrant leg ulcers are the most characteristic feature.^{325–331} It is caused by a mutation in the peptidase D (PEPD) gene that maps to 19cen–q13.11.³²⁸ Prolidase splits iminodipeptides found in collagen. Other clinical features that may be present include mental retardation, splenomegaly, recurrent infections, a characteristic facies, and premature graying of the hair.^{332–335} Telangiectasia, photosensitivity, lymphedema, and erosive cystitis³²⁶ are rare manifestations.³²⁵ The development of a squamous cell carcinoma in an ulcer is a surprisingly uncommon complication.³³⁶ Onset of symptoms occurs in childhood. Large amounts of iminodipeptides are present in the urine.³³⁷

An association with systemic lupus erythematosus has been found in at least 10 reported patients with prolidase deficiency, raising the question of whether the PEPD gene could be a modifier or risk factor in the development of lupus erythematosus.³³⁸

Apheresis exchange has produced improvement in the leg ulcers in this condition.³³⁹

Histopathology

The cutaneous ulcers may show secondary infection and variable fibrosis in chronic cases. Two reports have mentioned the presence of amyloid-like material in vessel walls and in the immediately adjacent dermis.^{340,341} Vascular wall thickening and infiltration of mononuclear cells and neutrophils have been observed in indurated lesions prior to their ulceration.³⁴² Although the dermal collagen in non-ulcerated areas appears normal on light microscopy, the fibers are seen to be smaller and irregularly patterned³³⁴ on electron microscopy. Elastic fibers are fragmented.³³⁴

TANGIER DISEASE

Tangier disease (OMIM 205400) is a rare autosomal recessive disorder of plasma lipid transport in which there is a deficiency of normal high-density lipoproteins (HDL) in the plasma and an accumulation of cholesterol esters in many organs, particularly in the reticuloendothelial system.³⁴³ The disorder was originally described in a kindred living on Tangier Island in Chesapeake Bay. The presence of enlarged yellowish tonsils and a low plasma cholesterol level is pathognomonic. The skin usually appears clinically normal, although small papular lesions have been described.³⁴⁴ The disorder is caused by a mutation in the ATP-binding cassette-1 gene (ABCI). Abnormalities in this gene also cause another disease characterized by HDL deficiency; that is, the two conditions are allelic. The gene responsible maps to chromosome 9q22–q31.

Histopathology

Biopsies from clinically normal skin show perivascular and interstitial nests of foam cells admixed with a few lymphocytes and plasma

cells.³⁴⁵ In frozen sections, the cytoplasm of the foam cells stains with oil red O and Sudan black.³⁴⁵ Doubly refractile cholesterol esters are demonstrable in both an intracellular and an extracellular location.³⁴⁵ In semithin sections, there is extensive vacuolization of the cytoplasm of Schwann cells in small, unmyelinated cutaneous nerves.³⁴³

Electron microscopy

The deposits are electron lucent and vary from spherical to crystalline in shape. They are not membrane bound. Lipid deposits are present in the cytoplasm of Schwann cells.³⁴³

LAFORA DISEASE

Lafora disease (myoclonic epilepsy; OMIM 254780) is a familial, degenerative disorder with the clinical triad of seizures, myoclonus, and dementia.^{346,347} Cutaneous lesions are rarely present.³⁴⁶ Lafora disease can be caused by mutations in the laforin (*EPM2A*) or the malin (*NHLRC1*) gene. Malin appears to regulate laforin protein concentrations.³⁴⁸ The genes responsible map to chromosome 6q23–q25.³⁴⁹ The OMIM gene map locus is listed as 6q24, 6p22.3. The intracytoplasmic inclusion bodies found in various organs, particularly in ganglion cells in parts of the brain, are glucose polymers called polyglucosans;^{346,350} they were first described by Lafora, who considered them to consist of amyloid.

Histopathology

The inclusion bodies (Lafora bodies, polyglucosan bodies) are well seen in the excretory ducts of eccrine and apocrine sweat glands of clinically normal skin.^{347,351,352} They are PAS positive and diastase resistant. The number of inclusions may vary with the biopsy site;³⁴⁶ axillary skin is favored.³⁴⁹

Electron microscopy

The inclusions are round or oval, non-membrane bound, and often juxtanuclear in position.^{128,347} They are composed of fine filamentous material, dark-staining granules, and vacuoles.³⁴⁶

ULCERATIVE COLITIS AND CROHN'S DISEASE

Ulcerative colitis and Crohn's disease (regional enteritis) have many cutaneous manifestations in common.^{353–357} Skin lesions occur in 10–20% of patients with either disease, but the incidence varies widely from one study to another, depending on the inclusion or otherwise of oral, perianal, and nonspecific lesions.^{353,354} In the case of Crohn's disease, cutaneous manifestations are more common in patients with colonic rather than ileal disease. The onset of skin lesions occasionally precedes the symptoms and signs of the inflammatory bowel disease. There is no correlation, as a rule, with the severity or activity of the bowel disease.

Erythema nodosum and pyoderma gangrenosum are the most common and specific cutaneous manifestations of *both diseases*, although pyoderma gangrenosum is more frequent in ulcerative colitis.^{358–360} Finger clubbing, aphthous ulcers of the mouth,³⁶¹ cutaneous polyarteritis nodosa,^{362,363} psoriasis,³⁶⁴ pyostomatitis vegetans,^{365–367} erythema multiforme,³⁶⁸ and vitiligo^{369,370} have been reported in both conditions.³⁵³ Inflammatory bowel disease was present in 21 of 29 patients with aseptic abscesses, characterized by deep, sterile abscesses involving particularly the spleen, liver, and lymph nodes.²⁴⁶ A small number of patients have a neutrophilic dermatosis.²⁴⁶ Cutaneous complications of therapy sometimes develop.

In *Crohn's disease*, the perianal manifestations include skin tags, fistulas, and abscesses.^{371,372} Anal skin tags may have multiple lobes and have been described as 'elephant ears'.³⁷³ The perianal tags may be confused clinically with condylomata acuminata, but biopsies can show

Figure 18.13 Crohn's disease. A small, noncaseating granuloma is in intimate contact with a small blood vessel in the lower dermis. There is extravasation of fibrin into the vessel wall. (H&E)

granulomatous dermal infiltrates and overlying acanthosis without viropathic changes.³⁷⁴ They are found in up to 80% of individuals with colonic involvement.³⁷⁵ Mucosal 'cobblestoning' and fissuring may occur in the mouth.^{376–378} Intraepithelial IgA pustulosis is a rare oral disease occurring in Crohn's disease,³⁷⁹ and a case of linear IgA disease associated with Crohn's disease has been reported.³⁸⁰ Cheilitis granulomatosa (see p. 210) may occur on the lips.³⁸¹ Other lesions described in Crohn's disease include erythema elevatum diutinum,³⁸² a vesiculopustular eruption,³⁸³ a neutrophilic dermatosis of the malar regions,³⁸⁴ epidermolysis bullosa acquisita,³⁸⁵ acne fulminans,³⁸⁶ pyoderma faciale,³⁸⁷ a neutrophilic lobular panniculitis,³⁸⁸ granuloma annulare/necrobiosis lipoidica-like lesions,³⁶⁰ leukocytoclastic vasculitis,³⁸⁹ granulomatous vasculitis (**Fig. 18.13**),^{360,390} porokeratosis, and nutritional deficiency states related to zinc, niacin (nicotinic acid), and vitamin C.^{353,376} Acrodermatitis enteropathica-like lesions have occurred in Crohn's disease due to zinc deficiency.³⁹¹ The occurrence of granulomas in nodular, ulcerated or plaque-like lesions, at sites well removed from involved mucosal surfaces, has been called '*metastatic Crohn's disease*'.^{392–403} Some lesions are in intertriginous areas; the limbs are another favored site.⁴⁰⁴ The vulva, breast,⁴⁰⁵ scrotum, and penis are rarely involved.^{406–412} Genital involvement appears to be more common in children than adults.^{413–416} There are noncaseating granulomas, similar to those seen in the bowel, scattered through the dermis and sometimes the subcutis. Granulomas with a slight cuff of lymphocytes are present in a nodular or diffuse pattern with an associated superficial and deep perivascular mixed inflammatory infiltrate.⁴¹⁷ Eosinophils are sometimes conspicuous.⁴¹⁷ Sometimes there are only occasional granulomas in a perivascular distribution (granulomatous perivasculitis).⁴¹⁸

Uncommon manifestations of *ulcerative colitis* include thromboembolic phenomena, cutaneous vasculitis,^{358,419,420} and a vesiculopustular eruption.⁴²¹ Some of the pustular lesions described in ulcerative colitis probably represent evolving lesions of pyoderma gangrenosum, others resemble Sweet's syndrome,^{422,423} and still others are nonspecific pustular eruptions.^{419,424–428} These may show either a suppurative folliculitis or intraepidermal or deeper abscesses. In short, a spectrum of neutrophilic dermatoses can occur.⁴²² Granulomas with admixed neutrophils were present in one proven case of ulcerative colitis.⁴²⁹

WHIPPLE'S DISEASE

Whipple's disease is a rare, multisystem, bacterial infection characterized by malabsorption, abdominal pain, arthritis, and neurological

manifestations. The organism responsible, *Tropheryma whippelii*, is related to the actinomycetes group of gram-positive bacteria.⁴³⁰ The cutaneous changes include hyperpigmentation of scars and sun-exposed skin, observed in approximately 40% of patients,⁴³¹ as well as hyperkeratosis, peripheral edema, petechiae and purpura,⁴³² erythema nodosum, and, rarely, subcutaneous nodules.^{433–435}

Histopathology^{433,436}

The subcutaneous nodules show a nonspecific panniculitis with pockets of foamy macrophages containing PAS-positive, diastase-resistant material and resembling those seen in small bowel biopsies.⁴³⁵ In a recent study, 13 patients with classic Whipple's disease but without skin manifestations underwent skin biopsies that yielded positive polymerase chain reaction results for *T. whippelii*.⁴³²

CYSTIC FIBROSIS

Cystic fibrosis (OMIM 219700) is an autosomal recessive disorder due to mutations in the cystic fibrosis conductance regulator (*CFTR*) gene. It occurs in 1 in 2500 live births in white populations.⁴³⁷ Cutaneous manifestations of malnutrition are seen infrequently in cystic fibrosis; they have been attributed to deficiencies of protein, zinc, and fatty acids.^{2,229,438,439} The lesions described include erythematous, desquamating papules and plaques and also scaling, sometimes annular, patches and plaques.⁴³⁸ Aquagenic skin wrinkling may develop at an early stage.⁴³⁷ An acrodermatitis enteropathica-like eruption has also been described.^{230,231} In another patient, the eruption resembled necrolytic migratory erythema.²⁸⁹ The lesions develop early in life. Electrochemical skin conductance is also abnormal in cystic fibrosis patients.⁴⁴⁰

Histopathology⁴³⁹

The changes are not diagnostically specific. They include acanthosis, a diminished granular layer with overlying parakeratosis, and a mild perivascular infiltrate of lymphocytes in the upper dermis. Mild spongiosis is sometimes present. The necrolysis and pallor seen in acrodermatitis enteropathica are absent.

DIABETES MELLITUS

Cutaneous manifestations are common in diabetics, occurring at some time in approximately 30% of all people who have the disease. Most of these skin complications and associations have been discussed elsewhere in this volume, but they are listed here for completeness. Three complications that have not been considered elsewhere – microangiopathic changes, pigmented pretibial patches (diabetic dermopathy), and bullous eruption of diabetes mellitus (bullous diabeticorum) – are discussed in detail later.

There are many ways of subclassifying the cutaneous manifestations and associations of diabetes mellitus.^{441–445} The one used here is based on the review published in 1982 by Huntley.⁴⁴⁶

Vascular and neuropathic complications

Both large and small vessels are affected in diabetes.⁴⁴⁶ Atherosclerosis of large vessels contributes to the ischemic complications, such as gangrene of the lower leg, but small vessel (microangiopathic) changes also play an important role. These latter changes are considered later. Other vascular-related phenomena include facial rubeosis⁴⁴² and the erysipelas-like areas of erythema sometimes seen on the lower parts of the legs, including the feet. Reduced sweating, loss of hair, and glazed skin are, in part, related to vascular changes.

Sensory, motor, and autonomic neuropathies may occur in diabetes. Autonomic dysfunction is sometimes associated with disturbances of sweating and vasomotor phenomena. Neuropathic ulcers may result

from the sensory neuropathy. Verrucous skin lesions have developed in association with these neuropathic ulcers on the feet.⁴⁴⁷

Infections

Infections are seen less commonly than in the past, probably because there is better control of diabetes. Bacterial infections that may occur include furuncles, nonclostridial gas gangrene, *Pseudomonas* infections of the ears, and erythrasma (see p. 647). Infections with *Candida albicans* are still common in diabetics and may result in paronychia, stomatitis, vulvitis, and balanitis (see p. 691). Dermatophyte infections may not be increased, as previously thought.⁴⁴⁸ Rare mycotic infections in diabetics include nocardiosis (see p. 708), cryptococcosis (see p. 693), and the zygomycoses (see p. 710). Protothecosis has also been reported in a patient with diabetes mellitus.⁴⁴⁹

Distinct cutaneous manifestations

Diabetes mellitus may be associated with the following conditions: necrobiosis lipoidica (see p. 203), granuloma annulare of the disseminated type (see p. 198), scleredema (also known as diabetic thick skin,⁴⁵⁰ see p. 413), pigmented pretibial patches (see later), bullous eruption of diabetes mellitus (see later), finger 'pebbles' that resemble knuckle pads histopathologically^{451–454} (see p. 976), and eruptive xanthomas (see p. 1162). In some diabetics, the skin is waxy and thickened, particularly over the proximal interphalangeal joints of the hands, leading to stiffness of the joints.^{446,455} Another manifestation is yellow skin, due in part to the carotenemia that is present in some diabetics.⁴⁴² A reduced threshold to suction-induced blisters has also been found in insulin-dependent diabetics.⁴⁵⁶

Less well-documented associations⁴⁴⁶ include skin tags (see p. 972), peripheral edema, yellow nails, and perforating disorders associated with diabetic renal failure and hemodialysis (see p. 373). Patients with diabetes mellitus tend to show a reduced hydration state of the stratum corneum, similar to senile xerosis, but there is no impairment of the barrier function of the stratum corneum.⁴⁵⁷

Diabetes mellitus or an abnormal glucose tolerance test is present in a small number of patients with Werner's syndrome (see p. 378), scleroderma (see p. 348), vitiligo (see p. 323), lichen planus (see p. 39), and Cockayne's syndrome (see p. 620) and also in relatives of patients with lipoid proteinosis (see p. 439).

Secondary diabetes mellitus⁴⁴⁶

Diabetes mellitus may occur as a secondary process in the course of a number of diseases, such as hemochromatosis (see p. 447), lipodystrophy (see p. 544), acanthosis nigricans (see p. 587), Cushing's syndrome, acromegaly, and the hepatic porphyrias, particularly porphyria cutanea tarda (see p. 577). These disorders have their own cutaneous expressions, in addition to any related to the diabetic state.

Complications of therapy⁴⁴⁶

The use of oral hypoglycemic agents may be complicated by a maculopapular eruption, urticaria, photosensitivity, and flushing when alcohol is consumed (with chlorpropamide) and very rarely by erythema multiforme, exfoliative dermatitis, or a lichenoid eruption.

Localized reactions to the injection of insulin are not uncommon and include allergic reactions, localized induration, anesthetic nodules composed of hypertrophied fat and some fibrous tissue, focal dermal atrophy, ulceration and necrosis, brown hyperkeratotic papules, keloid formation, and localized hyperpigmentation. Insulin-induced lipoatrophy is another complication that may develop 6–24 months after the onset of therapy.⁴⁵⁸ It is more common in young females, particularly in areas of substantial fat deposition. The atrophy sometimes occurs at sites remote from injections.⁴⁴¹ Lipohypertrophy presents as a soft swelling resembling a lipoma. It is more common in males.⁴⁴¹ Generalized allergic reactions may also occur; these are more common with beef insulin than pork insulin.⁴⁵⁸

Diabetic microangiopathy

Diabetic microangiopathy refers to the abnormal small vessels found in many organs and tissues in diabetes mellitus. The kidneys, eyes, skin, and muscles are particularly affected by this disease process, which is the principal factor determining the prognosis of individuals with diabetes mellitus.⁴⁴¹

Microangiopathy may be involved in the pathogenesis of the pigmented pretibial patches, the erysipelas-like erythema, and the necrobiosis lipoidica that may occur in diabetes mellitus. It may contribute to the neuropathy that sometimes occurs. Small vessel disease may be as important as atherosclerosis of large vessels in producing gangrene of the feet and lower limbs in diabetics. In many instances, the microangiopathy is clinically silent.

Histopathology

There is thickening of the walls of small blood vessels in the dermis and subcutis and some proliferation of their endothelial cells. The thickening of the walls and subsequent luminal narrowing is caused by the deposition of PAS-positive material in the basement membrane region. This material is partially diastase labile, although most of it is not.⁴⁵⁹ Membranocystic lesions, in which a thin hyaline zone surrounds a small 'cystic' space, have been reported in the subcutaneous fat (see p. 547).⁴⁶⁰

Granular and homogeneous deposits of C5b-9, along with homogeneous deposits of immunoglobulin within the blood vessels, are a characteristic finding.⁴⁶¹ Similar deposits are found in porphyria cutanea tarda.⁴⁶¹

Electron microscopy

The walls of the small vessels are thickened by multiple layers of veil cells (a fibroblast-like cell) and of basement membrane material.^{460,462} There may also be some deposition of collagen in the walls of small vessels in the dermis.⁴⁶²

Pigmented pretibial patches

Pigmented pretibial patches (diabetic dermopathy, skin spots) are the most common cutaneous finding in diabetes mellitus, although they are not specific to it.^{446,463} They are found in up to 50% of diabetics, but because they are asymptomatic, they are usually overlooked.⁴⁶⁴ The patches are seen more frequently in older patients and in those who have had diabetes mellitus for a longer period of time.⁴⁶⁵ They begin as flat-topped, dull-red papules that are round or oval, discrete or grouped, and situated mainly on the pretibial areas.⁴⁴¹ Involvement of the forearms and thighs has been recorded.⁴⁶⁶ As the lesions evolve, they develop a thin scale and finally become variably atrophic and hyperpigmented.^{442,458} They vary from 0.5 cm in diameter up to large patches covering much of the pretibial skin.

It has been suggested that the lesions represent an exaggerated response to trauma in skin overlying bony prominences⁴⁴⁶ and that there may be an underlying diabetic angiopathy.^{467,468} Blood flow levels are considerably higher at the dermopathy sites than at contiguous uninvolved skin sites, refuting the theory that they are ischemic in origin.⁴⁶⁹ However, further studies have shown that there is a reduction in blood flow in normal-appearing pretibial skin of those with diabetic dermopathy compared to a diabetic control group or normal controls.⁴⁷⁰ The authors postulated that this low skin perfusion may not permit wound healing without the scarring process associated with diabetic dermopathy.⁴⁷⁰ The presence of pigmented pretibial patches has an unfavorable association with the three most common microangiopathic complications of diabetes mellitus: neuropathy, nephropathy, and retinopathy.⁴⁶⁵ A relationship between these patches and coronary artery disease has also been demonstrated.⁴⁶⁵

Histopathology⁴⁷¹

In the early lesions, which are infrequently biopsied, there is edema of the papillary dermis and a mild perivascular lymphocytic infiltrate with some extravasation of red blood cells.⁴⁴⁶ There may be mild epidermal spongiosis and focal parakeratosis. Hyaline microangiopathy is invariably present.⁴⁶⁸

In atrophic lesions, there is neovascularization of the papillary dermis, a sparse perivascular infiltrate of lymphocytes, and small amounts of hemosiderin, mostly in macrophages. Attention has been drawn to the presence of a few perivascular plasma cells in this condition, but plasma cells are almost invariably present whenever there is hemosiderin deposition in the skin.⁴⁶⁸ In a case studied by the author, hemosiderin was also present in the epidermis, between basal cells and along the basement membrane – a finding not previously recorded. A recent study found plasma cells in 3 of 14 cases. A minority showed moderate to severe thickening of the walls of arterioles or medium-sized arteries. Capillary basement membrane thickening was frequently present, though mild, and well demonstrated with a PAS stain.⁴⁷² Ten of 14 cases had both iron and melanin deposition in the dermis.⁴⁷²

Bullous eruption of diabetes mellitus (bullosis diabeticorum)

Bullae, usually multiple and confined to the lower extremities, are a rare complication of long-standing diabetes mellitus.⁴⁷³ They were originally reported in 1963 as 'phlyctenar lesions' because they become dark as they dry up, in the manner of a burn blister.⁴⁷⁴ The bullae, which arise on a non-inflamed base, are tense and vary in diameter from 0.5 to 17 cm.^{458,475} They heal in several weeks, usually without scarring.

It seems likely that cases reported under this title do not represent a homogeneous entity, with some possibly representing the bullous dermopathy of chronic renal failure.^{446,476} Wang and Ackerman concluded their review on bullosis diabeticorum by supporting this view that it is not a discrete entity.⁴⁷⁷ Furthermore, there is an increased frequency of diabetes in patients with bullous pemphigoid.⁴⁷⁸

Histopathology⁴⁷³

The majority of the bullae reported under this title have been intraepidermal in location, often with spongiotic changes in the surrounding epidermis.⁴⁷⁹ It has been suggested that some of these may represent healing subepidermal blisters. In other cases, the split has been subepidermal,^{473,480–482} immediately beneath the lamina densa.⁴⁸³ Although it has been claimed that these have been early lesions and, as such, may more accurately reflect the true histological picture,⁴⁸³ it should be noted that in the majority of cases with subepidermal blisters, diabetic nephropathy has been present.^{476,483} The drugs being taken by these patients, a potentially important etiological aspect, have not been listed. In the author's experience, the bullae have been subepidermal in location; the editor has seen one example with both intraepidermal and subepidermal separation. Basal cell degeneration also occurs in some cases (Fig. 18.14).

The bullae contain fibrin and just a few inflammatory cells, but there is no acantholysis. There may be diabetic microangiopathy with thickening of the walls of small dermal blood vessels, but there is usually only a sparse perivascular lymphocytic infiltrate.⁴⁸⁰

Direct immunofluorescence is negative.

PORPHYRIA

The porphyrias are a clinically and biochemically heterogeneous group of disorders in which there are abnormalities in the biosynthesis of heme, leading to the increased production of various porphyrin

Figure 18.14 Bullosis diabeticorum. (A) This lesion shows predominantly subepidermal separation, but with a degree of basal cell degeneration. Thickening of the walls of small blood vessels is present. (B) In this case, there are both intraepidermal and subepidermal separation. Spongiotic changes are present; in addition, there is focal basal cell degeneration. (H&E)

precursors.^{484–495} The various enzyme deficiencies are not always accompanied by detectable increases in the relevant substrate, and overproduction of the precursors does not necessarily lead to symptomatic disease. However, the homozygous state for a particular enzyme deficiency is probably always clinically overt. The various enzyme deficiencies do not result in heme deficiency because a compensatory increase in substrate concentration is sufficient to restore the rate of heme synthesis to normal.⁴⁹⁶

Traditionally, the porphyrias have been classified on the basis of the primary site of overproduction of porphyrins.⁴⁹⁷ In the *erythropoietic porphyrias* (congenital erythropoietic porphyria and erythropoietic protoporphyria), there is disordered synthesis of heme in the bone marrow.⁴⁹⁸ In the *hepatic porphyrias* (acute intermittent porphyria, ALA-dehydratase deficiency, hereditary coproporphyria, variegate porphyria, porphyria cutanea tarda, and hepatoerythropoietic porphyria), there is disordered synthesis of heme in the liver.⁴⁹⁷ In some circumstances, both sites are involved.

It is more appropriate to classify the porphyrias on the basis of their clinical manifestations. Three categories are then recognized:

1. *Porphyrias with acute episodes and no cutaneous signs*

- Acute intermittent porphyria
- ALA-dehydratase deficiency

2. *Porphyrias with acute episodes and cutaneous signs*

- Hereditary coproporphyria
- Variegate porphyria

3. *Porphyrias with cutaneous signs only*

- Congenital erythropoietic porphyria
- Erythropoietic protoporphyria
- Porphyria cutanea tarda
- Hepatoerythropoietic porphyria.

In addition to these eight types of porphyria, there are rare variants that defy classification.⁴⁸⁵ Such cases include neonates who develop a photosensitive eruption due to a transient porphyrinemia resulting from phototherapy for hemolytic disease of the newborn.^{499,500}

The *acute episodes* referred to previously are characterized by abdominal pain, neurological changes, and psychiatric disturbances.^{485,501} Sometimes these acute episodes are precipitated by exogenous factors such as drugs.⁵⁰² The *cutaneous manifestations* are of two types.⁵⁰³ There may be an acute flare pattern with rapidly evolving, painful and burning lesions with some erythema and edema.⁵⁰⁴ This pattern is typical of erythropoietic protoporphyria, although it occurs rarely in some of the other variants (see later). The other cutaneous pattern (seen in hereditary coproporphyria, variegate porphyria, congenital erythropoietic porphyria, porphyria cutanea tarda, and hepatoerythropoietic porphyria) consists of slowly developing skin fragility with the development of blisters, erosions, and scars.^{504–506} These aspects are considered in further detail with each particular variant of porphyria (see later).

Biosynthesis of porphyrins

Glycine and succinyl coenzyme A react in the presence of ALA-synthase to form δ -aminolevulinic acid (ALA).⁴⁸⁷ This is converted to porphobilinogen and subsequently to protoporphyrin IX by a series of enzymatic reactions (Table 18.1). Protoporphyrin IX is chelated with iron in the presence of ferrochelatase to form heme.⁵⁰⁷

Acute intermittent porphyria

Acute intermittent porphyria (OMIM 176000) is an autosomal dominant disorder resulting from a defect in porphobilinogen deaminase (uroporphyrinogen I synthase) that catalyzes the formation of uroporphyrinogen from four molecules of porphobilinogen.⁵⁰⁸ The gene encoding this enzyme is at 11q23.3. The disorder is usually latent, but acute episodes consisting of neurological, psychiatric, and abdominal symptoms may be precipitated by various factors, particularly drugs.⁵⁰⁹ Barbiturates, sulfonamides, and griseofulvin are most often incriminated.⁵⁰² There are no cutaneous manifestations.

Laboratory findings include greatly increased levels of porphobilinogen and ALA in the urine during, and usually between, attacks.

ALA-dehydratase deficiency porphyria

This very rare, autosomal recessive disorder (OMIM 125270) results, as its name indicates, from a deficiency of ALA-dehydratase which was formerly known as porphobilinogen synthase (PBG-synthase). The gene encoding this enzyme is at 9q34. There are intermittent, acute episodes resembling those in acute intermittent porphyria; there are no cutaneous manifestations.⁵⁰⁹

The pattern of overproduction of heme precursors closely resembles that seen in severe lead poisoning. There is overproduction of ALA and of coproporphyrinogen III.

Hereditary coproporphyria

Hereditary coproporphyria (OMIM 121300) is an autosomal dominant variant of acute porphyria that results from a deficiency of

Table 18.1 Summary of the biosynthesis of heme and the associated clinical disorders		
Metabolites	Enzymes	Porphyrias
Glycine + succinyl CoA		
↓	ALA-synthase	
Aminolevulinic acid		
↓	ALA-dehydratase	ALA-dehydratase deficiency

coproporphyrinogen oxidase.⁵⁰⁴ The gene encoding this enzyme, the coproporphyrinogen oxidase (CPOX) gene, is at 3q12. Multiplex ligation-dependent probe amplification (MLPA) is considered a useful complement to gene sequencing for genetic diagnosis of this disorder.⁵¹⁰ Latent disease is more usual than the symptomatic form, which is characterized by episodic attacks of abdominal pain and neurological and psychiatric disturbances. These acute episodes are less severe than in acute intermittent porphyria. Cutaneous photosensitivity occurs in approximately 30% of cases and becomes manifest chiefly in association with the acute attacks.^{504,511} The lesions resemble those seen in porphyria cutanea tarda (see later). There has been one report of a patient with porphyria-like photosensitivity following liver transplant. The coproporphyrin levels were only mildly elevated.⁵¹² Acute coproporphyria has also been induced by the anabolic steroid methandrostenedolone (methandienone).⁵¹³

Laboratory findings include greatly elevated levels of urinary and fecal coproporphyrins. Porphobilinogen and ALA are increased, as in variegate porphyria (discussed next), during acute episodes.⁵¹¹ Infusions of heme arginate, a product of human hemin, have been effective in managing the severe attacks associated with hereditary coproporphyria.⁵¹⁴ This agent functions, as does hematin, by inhibiting the heme biosynthesis feedback mechanism, thereby preventing the accumulation of phototoxic precursors, but it is considered more stable. Side effects include infusion site pain, swelling, and phlebitis.⁵¹⁴

Variegate porphyria

Variegate porphyria (OMIM 176200), like hereditary coproporphyria, may be associated with acute episodes (as seen in acute intermittent porphyria) and with photocutaneous manifestations (as seen in porphyria cutanea tarda).^{515,516} It is an autosomal dominant disorder in which the activity of the enzyme protoporphyrinogen oxidase (the penultimate enzyme in the pathway of heme biosynthesis) is reduced by approximately 50%. This disorder is quite common in white Afrikaners and much less so in other white people and in people of other

racess.⁵¹⁵ The PPOX gene, which controls the formation of the responsible enzyme, maps to chromosome 1q22–q23.⁵¹⁷ Homozygous cases of variegate porphyria are rare; they present with severe photosensitivity in childhood.⁵¹⁸ Numerous mutations in this gene have been described in European patients, but in South Africa most patients have inherited the same mutation.^{519–523} A founder mutation has also been reported from Chile.⁵¹⁸ The simultaneous occurrence of symptoms of variegate porphyria has been reported in monozygotic twins.⁵²⁴

Only a minority of people with the enzyme defect develop clinical manifestations, and only after puberty. The clinical penetrance of variegate porphyria in one large South African family with the R59W mutation was 40%.⁵²⁵ It has been suggested that King George III of Great Britain may have had this disease, but the authors of a recent study suggest that this diagnosis is implausible based on the rarity of the disease, the limited clinical penetrance, the nature of the symptoms, and the lack of a supportive family history.⁵²⁶

Acute episodes are precipitated by exogenous factors such as the ingestion of various drugs.^{502,527} Cutaneous changes include skin fragility, blistering, and milia formation in sun-exposed areas, as in porphyria cutanea tarda, although very occasionally an acute phototoxic reaction (as seen in erythropoietic protoporphyria) may develop.⁵⁰⁴ Variegate porphyria is not usually associated with liver dysfunction, although it has been reported in association with a hepatocellular carcinoma.^{528,529} People with acute hepatic porphyrias such as variegate porphyria may have a 36- to 61-fold increased risk of developing hepatocellular carcinoma.⁵³⁰ Dapsone, used in the treatment of dermatitis herpetiformis, has precipitated an acute attack of variegate porphyria.⁵³¹ Complication of variegate porphyria by AA amyloidosis has been reported in one patient, possibly related to that patient's seronegative arthropathy.⁵³²

Laboratory findings are somewhat variable, depending on the activity of the disease.⁵⁰⁴ There is usually an elevated plasma porphyrin level with plasma fluorescence that is maximal at a wavelength of 626 ± 1 nm.⁵³³ In practice, the diagnosis is most often suggested by finding elevated levels of fecal protoporphyrin and coproporphyrin.⁵²⁷ Urinary ALA and porphobilinogen are usually increased during acute episodes.

Porphobilinogen deaminase activity is sometimes decreased as a secondary phenomenon.⁵³⁴

It has been reported in one homozygote that the erythrocyte protoporphyrin was raised and that this was predominantly zinc chelated.⁵³⁵

Antioxidant therapy (supplementation of vitamins E and C) appears to restore PPOX expression and may be beneficial in some patients with variegate porphyria.⁵³⁶

Congenital erythropoietic porphyria (Günther's disease)

Congenital erythropoietic porphyria (OMIM 263700) is a rare, autosomal recessive disorder of heme synthesis resulting from a deficiency of uroporphyrinogen III cosynthase (URO-synthase) that leads to an accumulation of porphyrins, particularly uroporphyrinogen I and III, in the bone marrow, blood, and other organs.^{537–540} The URO-synthase gene has been localized to the narrow chromosomal region 10q25.3–q26.3.⁵³⁸ Several different mutations have been described;⁵⁴¹ some specific mutations appear to correlate with a milder disease.⁵⁴² The defect leads to a chronic photobullous dermatosis, intermittent hemolysis, and massive porphyrinuria.⁵³⁷ Presentation is usually in infancy with red urine that stains diapers a pink color.⁵⁰⁴ Late onset of the disease has been reported in 15 cases.^{543–545}

The severe photosensitivity leads to the formation of bullae within a day or two of exposure to the sun. Recurrent eruptions may lead to mutilating deformities of the hands and face and sclerodermoid thickening of affected parts.⁵⁴⁶ Squamous cell carcinoma of the skin is a rare complication.⁵⁴⁷ Sunlight avoidance is the best therapy.⁵⁴⁰ Other clinical features include the pathognomonic characteristic of erythrodontia (discoloration of the teeth under normal light and red fluorescence with ultraviolet light), hypertrichosis, patchy scarring alopecia, and nail changes.^{537,548–550}

There are large amounts of uroporphyrins in the urine and coproporphyrins in the stool; these are predominantly type I isomers.⁵⁴⁶ The plasma and erythrocytes contain increased levels of uroporphyrinogen and, to a lesser extent, coproporphyrinogen.⁵⁵¹ Heterozygotes have blood levels of URO-synthase activity intermediate between affected individuals and controls.⁵⁴⁶

In the more severely affected individuals, bone marrow transplantation is potentially curative, but it is not without risks.^{552–554} There is also potential promise of proteasome inhibitors⁵⁵⁵ and gene therapy using induced pluripotent stem cells⁵⁵⁶ in this disease.

Erythropoietic protoporphyria

Erythropoietic protoporphyria (OMIM 177000), more recently termed simply 'protoporphyria',^{504,557} results from a defect in the terminal step of heme synthesis at which protoporphyrin IX and iron combine to form heme.^{558–562} It is associated with a partial deficiency of ferrochelatase (heme synthase) leading to an accumulation of protoporphyrin IX in erythrocytes, plasma, liver, and skin.⁵⁶³ Although originally regarded as autosomal dominant in inheritance, it is now known that autosomal recessive inheritance occurs in a few cases.^{561,564,565} In fact, recent investigations suggest that pseudodominant inheritance is the most common inheritance mode;^{566,567} this occurs with inheritance of a recessive genetic trait from a homozygous and a heterozygous parent. The gene for ferrochelatase (FECH) has been cloned and mapped to the long arm of chromosome 18 (18q21.3). More than 110 different mutations have been described.^{565–571} The presence of liver disease appears to correlate with specific mutations.⁵⁷⁰ Less often, there is a mutation of the δ -aminolevulinate synthase 2 (ALAS2) gene, associated with X-linked dominant disease.^{566,567}

It generally becomes manifest in early childhood with episodes of acute photosensitivity accompanied by a painful, burning sensation.⁵⁵⁹ Often, there is edema and erythema, and rarely there may be

urticaria and petechiae.^{504,572} The changes develop within a few hours of exposure to the sun. In the chronic stages, there is waxy scarring of the nose, radial scars around the lips, and pits or scars on the forehead, nose, and cheeks.^{504,573} The skin on the dorsum of the hands has a leathery texture, and it may also show 'cobblestone' thickening.⁵⁰⁴ It has a marked impact on quality of life.⁵⁶³ Deaths from cirrhosis accompanying heavy accumulation of protoporphyrin in the liver have been reported.^{574–577} Cirrhosis and liver failure occur in less than 5% of patients, but up to 20% may have abnormalities in liver function.⁵⁶⁵

Rare clinical presentations have included late onset,^{573,578,579} the presence of scarring bullae and milia,⁵⁸⁰ coexistence with lupus erythematosus,⁵⁸¹ a clinical picture resembling hydroa estivale⁵⁸² (see p. 624), and the presence of a fibrous band involving a digit (pseudoinhum).⁵⁸³ Late-onset disease often occurs in association with myelodysplastic syndrome,⁵⁸⁴ often the sideroblastic anemia subtype.⁵⁸⁵ Acquired erythropoietic protoporphyria has been reported in two patients as a result of myelodysplasia causing loss of chromosome 18, the locus of the ferrochelatase gene.^{585,586} In one group of patients with protoporphyria, the disease appears to be exacerbated by the ingestion of iron,⁵⁵⁸ in rare patients, there is symptomatic response to iron supplementation.⁵⁸⁷ Exacerbation has also followed blood transfusion.⁵⁸⁸ Clinical improvement, with lower erythrocyte porphyrin levels, occurs during pregnancy.^{589,590} Amelioration of photosensitivity from this disease has also been observed during breast-feeding.⁵⁹¹

Protoporphyria is the only disorder of porphyrin metabolism with normal urinary porphyrins.⁵⁰⁴ There are markedly increased levels of protoporphyrin in the feces and blood. The erythrocytes show a red fluorescence that decays more rapidly than that in congenital erythropoietic porphyria (discussed previously).⁵⁰⁴

Advice about sun avoidance and sun-protective measures should always be given. These patients are at risk for the subsequent development of vitamin D deficiency.⁵⁹² Narrowband UVB desensitization phototherapy has been given to patients prior to their holidays so that they might be asymptomatic during such a period.⁵⁷⁹ Bone marrow transplantation may also be used for long-term control.⁵⁹³

Porphyria cutanea tarda

Porphyria cutanea tarda (PCT; OMIM 176100) is the most common form of porphyria in Europe and North America.^{504,594} Its prevalence ranges from 1:5000 to 1:25,000 people.⁵⁹⁵ It is not a single disorder but, rather, an etiologically diverse group that share in common reduced activity of uroporphyrinogen decarboxylase (UROD), the enzyme that catalyzes the sequential decarboxylation of uroporphyrinogen to coproporphyrinogen in a two-stage process.^{504,596,597} In most forms, there is a reduction in hepatic UROD, leading to overproduction of porphyrins in the liver.⁵⁹⁸ In the uncommon familial form, there is usually a deficiency of this enzyme in erythrocytes as well as in other tissues.

There are three major forms of PCT: familial, sporadic, and toxic. In addition, the porphyria resulting from porphyrin-producing tumors of the liver^{596,599} and that associated with chronic renal failure and UROD deficiency are sometimes categorized as two further clinical variants of PCT.^{598,600–604} Hepatoerythropoietic porphyria (see below) is regarded as the homozygous deficiency of UROD.⁵⁹⁸

The *familial form* (type II) is inherited as an autosomal dominant trait.⁵⁹⁸ Numerous different mutations have been described.^{605,606} The enzyme (UROD) is located on chromosome 1p34.⁶⁰⁷ The familial form was previously thought to be associated, invariably, with a deficiency of UROD in erythrocytes as well as in the liver, but cases with a normal level of erythrocyte UROD have been documented.⁶⁰⁸ Sometimes, overt disease is precipitated by some exogenous factor such as childbirth, exposure to ultraviolet radiation in tanning parlors, iron overload, or excessive alcohol intake.^{594,609} Its onset is usually earlier than

that of the sporadic form.⁶¹⁰ Type III PCT is characterized by a family history of the disease, although it is biochemically indistinguishable from the sporadic form.⁶⁰⁵

The *sporadic form* (type I) usually has its onset in mid-life. More than 70% of cases in the past were associated with alcohol abuse and liver damage.^{598,611,612} Now, there is a virtual ‘epidemic’ of cases associated with hepatitis C virus, some of whom also develop hepatocellular carcinoma.^{613–620} The prevalence of hepatitis C infection in one Argentinean study was 35.2%.⁵⁹⁵ It has been suggested that the porphyria subtype should be called ‘chronic hepatic porphyria’.⁶²¹ Estrogen therapy for carcinoma of the prostate^{622,623} or for menopausal symptoms is sometimes the precipitating event. The menopause itself has also been incriminated; menstruation may act as a natural phlebotomy.⁶²⁴ Oral contraceptives have also been incriminated.⁶²⁵ A case of porphyria cutanea tarda was apparently induced by tamoxifen therapy.⁶²⁶ Improvement in the disease has resulted from the use of anastrozole to treat a patient with concurrent carcinoma of the breast.⁶²⁷ Anastrozole, an aromatase inhibitor, suppresses estrogen. Rare associations have included solar urticaria,⁶²⁸ Wilson’s disease,⁶²⁹ hepatocellular carcinoma,^{596,630} lymphoma,⁶³¹ HIV infection,^{632–635} agnogenic myeloid metaplasia,⁶³⁶ idiopathic myelofibrosis,⁶³⁷ lupus erythematosus,^{638–641} and diabetes mellitus.⁶¹¹ Alterations in glucose metabolism are actually prevalent in patients with PCT, tend to occur long after the diagnosis of porphyria, and develop in conjunction with iron overload and hepatic inflammation.⁶⁴² The sporadic form appears to result from inactivation of UROD in the liver,⁵⁹⁷ although this appears to be independent of, rather than the consequence of, liver injury.⁵⁹⁸ Mutations in the *HFE* gene associated with hereditary hemochromatosis have been associated with sporadic and familial PCT.^{607,643} There is a high prevalence of *HFE* gene mutations in patients with PCT in the Czech Republic.⁶⁴⁴ The C282Y mutation in the *HFE* gene appears to predispose patients to PCT.⁶⁴⁵ Co-inheritance of the genes for these two conditions appears to accelerate the onset of the porphyria.^{646,647} Phlebotomy should be first-line therapy in these patients because *HFE* C282Y homozygotes do not respond to chloroquine; response is limited to those patients with PCT and *HFE* wild type.⁶⁴⁸

The *toxic form* results from exposure to polychlorinated aromatic hydrocarbons.^{607,649} Other hepatotoxins have rarely been incriminated.

The cutaneous changes occur predominantly on light-exposed areas such as the face, arms, and dorsum of the hands.⁶⁵⁰ Their severity is highly variable. They include increased vulnerability to mechanical trauma and the formation of subepidermal vesicles or bullae measuring 0.5–3 cm in diameter.⁶¹¹ Erosions, milia, scars, and areas of hyperpigmentation are common.⁶¹¹ Hypertrichosis, patchy alopecia, darkening of gray hair,⁶⁵¹ infections,⁶⁵² dystrophic calcification, and sclerodermoid changes may occur but do so less frequently than the other cutaneous manifestations.⁶¹¹ The sclerodermoid changes, which may be present in up to 20% of cases, do not always occur in light-exposed areas. They may involve the scalp.^{653,654} They are not associated with sclerodactyly, and they are not invariably permanent. It has been suggested that they are related to high levels of uroporphyrinogen.⁶⁵⁵

Hepatic changes are common in PCT. There is an increased risk of developing hepatocellular carcinoma.⁵⁹⁶

Laboratory findings include increased amounts of uroporphyrins in the urine and plasma and of coproporphyrins in the feces. The urine contains a predominance of 8-carboxyl and 7-carboxyl porphyrins, whereas the feces contain isocoproporphyrin, which is not found in significant amounts in other porphyrias.⁵⁹⁷

Hepatoerythropoietic porphyria

Hepatoerythropoietic porphyria (OMIM 176100, as for PCT) is a rare, severe variant that is manifested clinically by photosensitivity commencing in early childhood.^{656–659} Fewer than 50 patients have been reported.⁶⁶⁰ As in PCT, there is a deficiency of UROD, but the activity

of this enzyme is much less than in PCT, reflecting a homozygous state.^{661,662} Several different point mutations and/or a deletion in the *UROD* gene on chromosome 1p34 have been reported.⁶⁶³ Hepatic involvement is common. The cutaneous features resemble those of PCT.⁶⁶⁴

Laboratory findings are similar to those in PCT, but an additional feature is the presence of elevated levels of protoporphyrins in erythrocytes.⁶⁵⁶

Pseudoporphyria

The term ‘pseudoporphyria’ is used for a phototoxic bullous dermatosis that resembles PCT.^{665,666} However, there are normal levels of porphyrins in the serum, urine, and feces.⁶⁶⁷ The term ‘therapy-induced bullous photosensitivity’ has been suggested as more appropriate⁶⁶⁸ because this condition has been reported following the use of a number of drugs, including tetracyclines,^{669,670} β -lactams (ampicillin-sulbactam and cefepime),⁶⁷¹ sulfonamides, isotretinoin,⁶⁷² ketoprofen,⁶⁷³ pravastatin,⁶⁷⁴ bumetanide, furosemide (frusemide),^{675,676} torsemide,⁶⁷⁷ nalidixic acid,⁶⁷⁸ ciprofloxacin,⁶⁷⁹ voriconazole,^{673,680} naproxen,^{681–684} celecoxib,⁶⁷³ rofecoxib,⁶⁸⁵ amiodarone,⁶⁸⁰ oxaprozin,⁶⁸⁶ mefenamic acid,⁶⁸⁷ aspirin,⁶⁸⁰ nabumetone,^{688–692} pyridoxine,⁶⁹³ chlorthalidone,⁶⁹⁴ the oral contraceptive pill,⁶⁹⁵ flutamide,⁶⁹⁶ cyclosporine (ciclosporin), 5-fluorouracil, excessive cola consumption,⁶⁸⁰ acitretin,⁶⁹⁷ etretinate,⁶⁹⁸ imatinib,^{699,700} finasteride,⁷⁰¹ and metformin.⁷⁰² A few cases have followed the prolonged use of tanning beds.^{703–705} Blistering has also been reported in patients with chronic renal failure undergoing hemodialysis.^{706,707} In one case, it followed the use of narrowband UVB phototherapy, used in the treatment of psoriasis.⁷⁰⁸ In some patients, pseudoporphyria has been associated with a deficiency of uroporphyrinogen decarboxylase with increased levels of porphyrins; in others, many of whom were also receiving furosemide (frusemide), the porphyrin levels have been normal.^{706,709,710} The various causes are listed in Table 18.2.

The lesions in pseudoporphyria, which consist of spontaneous blisters and skin fragility, usually involving the dorsum of the hands, may develop as early as 1 week or as late as several months after

Table 18.2 Drug and other causes of pseudoporphyria	
Acitretin	Hemodialysis
Amiodarone	Imatinib
Ampicillin-sulbactam	Isotretinoin
Aspirin	Ketoprofen
β -Lactams	Mefenamic acid
Bumetanide	Metformin
Cefepime (?)	Nabumetone
Celecoxib	Nalidixic acid
Chlorthalidone	Naproxen
Ciprofloxacin	Oxaprozin
Cola consumption	Pravastatin
Contraceptive pill	Pyridoxine
Cyclosporine (ciclosporin)	Rofecoxib
Dapsone	Sulfonamides
Etretinate	Tanning beds
Finasteride	Tetracyclines
5-Fluorouracil	Torsemide
Flutamide	UVB phototherapy
Furosemide	Vinblastine
	Voriconazole

commencement of the drug.⁶⁸¹ In contrast to PCT, few patients with pseudoporphyria develop hypertrichosis, hyperpigmentation, or sclerodermoid features.

Oral *N*-acetylcysteine has been used successfully in several cases of hemodialysis-associated pseudoporphyria.^{711,712}

The histopathologies of the different variants of porphyria are considered together.

Histopathology^{713–715}

There are remarkable similarities in the cutaneous changes in the various porphyrias: the differences are quantitative rather than qualitative.⁷¹⁴ The hallmarks of porphyria are the presence of lightly eosinophilic hyaline material in and around small vessels in the upper dermis, reduplication of vascular and sometimes epidermal basement membrane, and the deposition of fibrillar and amorphous material around the superficial vessels and at the dermoepidermal junction.^{713,714} The hyaline material seen on light microscopy is reduplicated basement membrane associated with the fibrillar and amorphous material just mentioned. Another distinctive feature seen in PCT, pseudoporphyria, and erythropoietic protoporphyria is so-called ‘caterpillar bodies’.^{716,717} They represent basement membrane material and colloid bodies, akin to the Kamino bodies of Spitz nevi (see p. 852), deposited in the basal layer of the epidermis as elongated segmented bodies or globules. They have a high specificity for PCT, but they were present in less than half of the cases in one study.⁷¹⁸ They are PAS positive and contain collagen IV (Fig. 18.15). The histological features of the various types of porphyria are discussed in further detail.

In *erythropoietic protoporphyria* (EPP), acute skin changes include a predominantly neutrophilic perivascular and interstitial dermal infiltrate, sometimes with leukocytoclasia, accompanied by endothelial cell vacuolization and cytolysis, with degranulated mast cells.⁷¹⁹ These vasculitis-like changes can dominate the histopathologic image and obscure a relatively subtle thickening of dermal vessel walls that can be demonstrated by PAS stain or (if available) by direct immunofluorescence.⁷²⁰ However, the best known changes are those of hyalinization, seen in more chronic lesions. This hyaline material not only involves the walls of small vessels in the papillary dermis but also forms an irregular cuff around these vessels (Fig. 18.16). There is variable thickening of the vessel walls as a consequence of the presence of this hyaline material, and this is sometimes associated with luminal narrowing. The hyaline material is strongly PAS positive and diastase resistant. It stains with

Sudan black in frozen sections, and it is weakly positive with Hale’s colloidal iron method.⁷²¹ It also stains, immunohistochemically, for laminin, collagen IV, and immunoglobulin light chains.⁷²² Elastic fibers are pushed aside by the hyaline material.⁷²¹ Uninvolved areas of skin in EPP show minimal or undetectable changes, suggesting that the interaction of solar radiation is mandatory for the vascular changes.⁷²²

In *porphyria cutanea tarda*, the hyaline material is restricted to the vessel walls and their immediate vicinity. It does not form a significant cuff as in EPP. Again, the material is PAS positive and diastase resistant. In some cases, there is PAS-positive thickening of the basement membrane. These changes are not usually present in early lesions of pseudoporphyria, although some PAS-positive material is found in vessel walls. Small amounts of this material may be found in vessel walls in clinically uninvolved skin in PCT.⁷¹³ Solar elastosis is usually present in PCT, a change that is not often seen in patients with EPP, which is a reflection of their younger age.⁷¹⁴ Dermal mast cells are increased in PCT.⁷²³

In *sclerodermoid lesions*, there is thickening of the dermis that may be indistinguishable from that seen in scleroderma, although a looser arrangement of the collagen fibers is usually discernible in PCT.^{713,714}

The *blisters* that form in the various forms of porphyria and in pseudoporphyria are subepidermal (dermolytic) with the dermal papillae projecting into the floor (festooning) (Fig. 18.17).^{681,724,725} This

Figure 18.15 *Porphyria cutanea tarda*. A ‘caterpillar body’ is present within the epidermis. It stains pink with the PAS stain. (PAS)

Figure 18.16 *Erythropoietic protoporphyria*. (A) Hyaline material surrounds vessels in the papillary dermis. (B) This case was initially misdiagnosed as a variant of colloid milium because of the extensive involvement of the papillary dermis. (H&E)

Figure 18.17 (A) Porphyria cutanea tarda. (B) There is a cell-poor, subepidermal bulla with some 'festooning' in the base. (H&E)

Figure 18.18 Pseudoporphyria. There is some 'festooning', but the vessels within these areas have only thin walls. (H&E)

latter change is not always prominent in pseudoporphyria.⁶⁸¹ There is only a very sparse inflammatory cell infiltrate, which in pseudoporphyria may sometimes include a rare eosinophil (**Fig. 18.18**). Focal hemorrhage is sometimes present in the upper dermis. The PAS-positive basement membrane is usually found in the roof of the blister.⁶⁸¹ Studies of laminin and type IV collagen suggest that the split in PCT and pseudoporphyria occurs in the lamina lucida.⁷²⁶

Epidermal changes are usually mild in the various porphyrias. The epidermis in PCT may be normal, acanthotic, or atrophic.⁷¹⁴ There is sometimes hyperkeratosis and mild hypergranulosis. In sclerodermoid lesions and in EPP, there is sometimes effacement of the rete ridge pattern.

Direct immunofluorescence in the porphyrias reveals deposits of IgG and, less commonly, IgM and complement in and around the upper dermal vessels.⁷²⁷ Granular and homogeneous deposits of C5b-9 within the blood vessels are a characteristic feature in PCT.⁴⁶¹ Small deposits may also be found at the dermoepidermal junction.⁵⁵⁹ Type IV collagen and laminin are additional components of the vascular and perivascular hyaline material that may be detected using monoclonal antibodies.^{703,714} In PCT, patients in clinical remission continue to show deposits of immunoglobulin in the walls of blood vessels and along the dermal-epidermal junction, but complement deposits are reduced in most instances.⁷²⁸

Electron microscopy^{713,714}

There is prominent reduplication of the basal laminae with encasement of the vessels in a concentric manner. External to the laminae, there is finely fibrillar material that also extends into the vessel wall.⁷¹³ Irregular clumps of amorphous material are also found in the perivascular regions.

Fine collagen fibrils are present within and around the vessels in the upper dermis, whereas the sclerodermoid lesions have fibrils with a bimodal size throughout the dermis.⁷²⁹

The 'caterpillar bodies' of PCT appear to be a combination of degenerating keratinocytes, colloid bodies, and basement membrane bodies.⁷¹⁷

Another ultrastructural finding in some of the porphyrias is reduplication of the basal lamina at the dermoepidermal junction. This is seen in PCT and variegate porphyria but not usually in EPP.

In blisters, the cleavage is usually dermolytic, with the roof containing a thin layer of dermal fibers still attached to the anchoring fibrils.⁷¹⁴ Early lesions appear to develop from the enlargement of

membrane-limited vacuoles in the upper dermis.⁷³⁰ Some of these appear to form in the pseudopodia of basal cells that protrude into the dermis.⁷³⁰

Finally, in one study of an acute flare reaction in EPP, endothelial cell damage was noted, leading to the suggestion that leakage of vascular contents contributes to the hyaline material.^{731,732} The reduplication of the basal lamina may represent a reparative reaction to repeated endothelial injury.

Differential diagnosis

The constellation of microscopic features enumerated previously is characteristic of the various types of porphyria. The differential diagnosis for bullous lesions includes the group of infiltrate-poor subepidermal blistering disorders: hereditary epidermolysis bullosa; bullosis diabetorum; infiltrate-poor pemphigoid; and some blisters due to extrinsic injury, such as suction or cryotherapy bullae. 'Festooning' at the blister base can occur in a number of these disorders, particularly epidermolysis bullosa and infiltrate-poor pemphigoid. However, the thickened basement membrane material at the dermal-epidermal junction and around vessels seen in forms of porphyria is not encountered in those disorders. Direct immunofluorescence findings can also be helpful in that the smudged-appearing basement membrane zone and perivascular fluorescence (particularly for IgG) is particularly characteristic of porphyrias. Caterpillar bodies are characteristic findings in the blister roof in forms of porphyria, but they do not represent a particularly sensitive finding because, as noted previously, they are seen in less than half of cases. At the same time, morphologically similar structures, known as 'caterpillar body-like structures', have been

described in porphyria cutanea tarda and erythropoietic protoporphyria as well as pseudoporphyria, bullous impetigo, bullous pemphigoid, and junctional and dystrophic forms of epidermolysis bullosa.⁷¹⁸ These structures are less intensely eosinophilic than true caterpillar bodies, and they are PAS and collagen IV negative.

It has been suggested that bullosis diabetorum may be a variant of porphyria or pseudoporphyria, particularly in those cases associated with renal failure. This requires further investigation. As noted previously, some examples of bullosis diabetorum show intraepidermal rather than subepidermal separation, but this may be the result of epidermal regeneration at the blister base. The hyaline material seen in skin biopsies of EPP can bear a resemblance to amyloid, the material seen in colloid milium, or the deposits of the rare condition lipoid proteinosis. The perivascular distribution and type IV collagen content of the deposits in EPP differ from those of primary cutaneous amyloidosis and colloid milium. EPP deposits do not have the staining properties of amyloid and do not show either the relationship with elastic fibers of adult colloid milium or the derivation from apoptotic keratinocytes of juvenile colloid milium. The hyaline material does not usually encroach on the adjacent dermis as much as it does in lipoid proteinosis (see p. 439); furthermore, it does not involve the sweat glands.⁷³³ In difficult cases, other clinical and laboratory data can be decisive in distinguishing among these disorders.

Miscellaneous conditions

Accessory tragus	584	Umbilical lesions	586	Erythroderma	591
Supernumerary nipple	584	Relapsing polychondritis	586	Papuloerythroderma	592
Accessory scrotum	585	Acanthosis nigricans	587	Scalp dysesthesia	592
Ectopic tissues	585	Confluent and reticulated papillomatosis	589	Cutaneous emphysema	593
Cheilitis glandularis	585	Acrokeratosis paraneoplastica	590		

Not unexpectedly, there are conditions encountered in dermatopathology that defy orderly classification, having neither a consistent tissue reaction pattern nor a recognized infectious etiology. However, in the case of confluent and reticulated papillomatosis, current evidence does point to an infectious etiology. Papuloerythroderma has many features suggesting a relationship to mycosis fungoides. Reclassification of these two entities is likely in the near future.

ACCESSORY TRAGUS

Accessory tragi are usually found as solitary, dome-shaped papules and nodules, present at birth, usually in the preauricular region but sometimes in the neck, anterior to the sternomastoid muscle.¹⁻⁴ The cervical lesions have been regarded by some as a discrete but closely related entity, also of branchial origin:⁵ they have been reported as cervical auricles, 'wattles', and congenital cartilaginous rests.⁶⁻⁸

Accessory tragi may be multiple, including a linear arrangement,⁹ and sometimes bilateral.¹⁰ Rarely, they are associated with other syndromes of the first branchial arch, such as hemifacial microsomia (oculo-auriculo-vertebral spectrum (OAVS) or Goldenhar's syndrome (OMIM 164210)), in which a myriad of congenital anomalies have been described.^{9,11} In one recent case, a deletion in the region of 22q11.2 has led to speculation that this is a candidate gene for the syndrome,^{12,13} but there is also interest in the regions 14q32 and 14q21.2.¹⁴ Clinically, accessory tragi, including the lower cervical variants, are usually diagnosed as skin tags.

Histopathology¹

The lesions are polypoid elevations with a fibrovascular zone beneath the epidermis containing numerous hair follicles with small sebaceous glands sometimes attached (Figs. 19.1 and 19.2). Some of the follicles are of vellus type. Beneath this area, there is a zone of adipose tissue and usually a central core of cartilage. There is a prominent connective tissue framework in the fat, irrespective of the presence of cartilage.¹⁵ Eccrine glands are often present, and occasionally there are large nerve fibers and even Pacinian corpuscles.

In the cervical lesions, there is mature cartilage embedded in fibrous tissue. Striated muscle in continuity with the underlying platysma muscle may also be present in the core. Telogen hairs are not always present in cervical lesions, or at least their presence is not mentioned in the reports. Histological features of both hair follicle nevus (see p. 904) and accessory tragus can coexist in a single lesion. As a rule, the accessory tragus has abundant fat cells.¹⁶

The rare condition described as **dermatorynchus geneae** is a related first arch abnormality in which large amounts of striated muscle and sometimes bone form the central core of the elongated polypoid lesion.¹⁷ The lesions reported as striated muscle hamartomas are closely related morphologically; they were not in the preauricular region (see p. 1036).

SUPERNUMERARY NIPPLE

Polythelia, as the presence of supernumerary nipples is sometimes called, is a developmental abnormality found in approximately 1% of the population.¹⁹ Much less common is polymastia, the term used to describe the presence of two or more breasts. This rare phenomenon occurs mostly in the axilla, but other sites have been recorded.^{20,21} Polymastia refers to the presence of nipple, areola, and glandular tissue, and if areola is not present, the term supernumerary glandular tissue is more appropriate.^{22,23} Polythelia is more common in men,²⁴ whereas polymastia is more common in women. Familial cases of supernumerary nipple have been recorded.²⁵ The supernumerary structure is usually a solitary, asymptomatic, slightly pigmented, nodular lesion, often with a small, central, nipple-like elevation. It may occur

Figure 19.1 Accessory tragus. In this case, there is adipose tissue but no cartilage in the core. (H&E)

Figure 19.2 Accessory tragus. Numerous hair follicles, some of vellus type, are present. Sebaceous glands are not well developed. (H&E)

anywhere along the pathway of the embryonic milk line, particularly on the anterior aspect of the chest or the upper abdomen. Rarely, it is outside this line.^{26,27} Clinically, it resembles a nevus or fibroma. There is said to be an increased incidence of renal abnormalities in patients with a supernumerary nipple,²⁰ although other studies have failed to confirm this association.^{28–31} An increased risk of genitourinary malignancy among individuals with polythelia has been suggested.²⁴ Rarely, a small patch of hairs may be the only marker of underlying accessory breast tissue ('polythelia pilosa').³² Nipple adenoma has arisen in a supernumerary mammary gland,³³ and a lactation adenoma has been found in a supernumerary nipple.³⁴ Accessory breast tissue is rarely seen in a Becker's nevus.³⁵

Histopathology¹⁷

The appearances resemble those seen in the normal nipple and include epidermal thickening with mild papillomatosis and basal hyperpigmentation, the presence of pilosebaceous structures, variable amounts of smooth muscle, and mammary ducts that open into pilosebaceous ducts or enter the epidermis (Fig. 19.3). There may be some underlying breast tissue but, as already stated, complete supernumerary breasts are very rare.²⁰ The recently reported lactation adenoma arising in a

Figure 19.3 Supernumerary (accessory) nipple. There is smooth muscle and a ductal structure. (H&E)

supernumerary nipple featured circumscribed nodules composed of glands lined by secreting cuboidal cells with cytoplasmic vacuolization and hyperchromatic nuclei.³⁴

Clear cells of Toker, found in approximately 10% of normal nipples by routine hematoxylin and eosin (H&E) staining but in up to 83% by immunohistochemistry, have been demonstrated in 65% of accessory nipples using CK7 staining.³⁶

Dermoscopy of one case showed a central white area, central streak, and a very faint pigmented network at the periphery.³⁷

ACCESSORY SCROTUM

Accessory scrotum is the presence of scrotal skin outside of its normal location but without testicular tissue. It is usually found in the perineal or inguinal region.³⁸ A normal scrotum is also present. An accessory scrotum has been reported in a patient with a Becker's nevus (see p. 337). Two recent cases have been reported of perineal accessory scrotum attached to a lipoma.^{39,40} Also described is a patient with an accessory scrotum and unilateral tibial aplasia.⁴¹

Agenesis of the scrotum is an exceedingly rare event.⁴²

ECTOPIC TISSUES

There are isolated reports of the occurrence in the skin of ectopic tissue. Most cases represent embryological vestiges, but trauma (surgery or a gunshot injury) is the explanation for splenic tissue in the subcutaneous tissues of the abdomen.^{43–45} Ectopic bowel mucosa may follow congenital eversion or implantation after an –ostomy involving bowel.⁴⁶ Rarely, nephrogenic rests are found in the lumbosacral region, either with or without associated spinal dysraphism.⁴⁷

Other ectopic tissues reported in the skin have included thymus,⁴⁸ respiratory mucosa, salivary gland,⁴⁹ thyroid,⁵⁰ brain, thymus,⁵¹ and pancreas. There is one report of a subcutaneous thymoma, but it probably spread from its more usual location.⁵² Ectopic nail (onychoheterotopia) is a rare condition in which nail-like tissue occurs in a location other than the nail bed.^{53,54} Fewer than 50 cases have been recorded. It may be congenital or acquired, the latter usually following acute trauma or repeated minor injuries to the nail unit.^{53,54}

CHEILITIS GLANDULARIS

Cheilitis glandularis is a chronic inflammatory disorder affecting mucous glands and ducts of the lower lip. It appears to be a heterogeneous entity, which has been attributed in the past to hyperplasia of labial salivary glands.^{55–57} However, a critical review of reported cases does not support this explanation⁵⁸ except in a few cases.⁵⁹ It has been suggested that the condition includes cases of factitious cheilitis,^{60–62} premature and exaggerated actinic cheilitis, and cases with a coexisting atopic diathesis in which mouth breathing may play a role.⁵⁸ An immunohistochemical study of aquaporins (membrane proteins that conduct water in and out of cells while preventing the passage of ions and other solutes) has shown increased expression of aquaporin-2 and decreased expression of aquaporins-1 and -8, suggesting local alteration of water transport and salivary gland physiology in this condition.⁶³ A case has been reported of cheilitis glandularis superimposed on oral lichen planus.⁶⁴ It has also been reported in albinos.⁶⁵ Note that only mild swelling of the lip is needed to produce eversion, which in itself exaggerates the appearance of swelling.⁵⁸

Patients present with macrocheilia, usually confined to the lower lip.⁶⁶ There is often crusting and fissuring with a mucoid discharge. Salivary duct orifices may be prominent. Clinically, the lesions need to be distinguished from plasma cell cheilitis,⁶⁷ cheilitis granulomatosa (Melkersson–Rosenthal syndrome; see p. 210), and Ascher's

syndrome, in which there is acute swelling of the lip and eyelids (usually the upper) resulting from edema, inflammation, and a possible increase in size of labial and lacrimal glands, respectively.^{56,68-71}

Squamous cell carcinoma may sometimes supervene, which is further evidence that many cases have an actinic etiology.^{55,57,72}

Treatment involves elimination of aggravating factors, reinstating oral hygiene, and the use of lip balms and sunscreens. Topical or intralesional corticosteroids, antibiotics, topical 5-fluorouracil cream, cryotherapy, and surgical excision have all been used. In the patient referred to previously with concurrent oral lichen planus, treatment with topical tacrolimus and pimecrolimus was successful.⁶⁴

Histopathology

There is usually hyperkeratosis, focal parakeratosis, and sometimes inflammatory crusting. There is underlying edema, variable but usually mild chronic inflammation, and variable solar elastosis.⁵⁸ Although the minor salivary glands are usually said to be hyperplastic, one study showed no increase in their size or appearance compared to controls. Notwithstanding, enlargement of salivary glands with dilated ducts and some chronic inflammation have been present in some cases reported as cheilitis glandularis.⁵⁹ A major review of the English language literature on cheilitis glandularis listed the following as the most common histopathologic findings: chronic inflammation, ductal ectasia, oncocytic metaplasia of ducts and acini, mucin within dilated ducts, and fibrosis within minor salivary glands.⁷³

UMBILICAL LESIONS

The umbilicus is an important embryological structure, into which the vitelline (omphalomesenteric) duct and urachus enter. Remnants of either structure may give rise to lesions at the umbilicus, and rarely, vestiges of both may coexist.^{74,75}

The omphalomesenteric duct normally becomes obliterated early in embryonic life, but remnants may persist, producing an enteric fistula, an umbilical sinus, a subcutaneous cyst, or an umbilical polyp.^{76,77} The latter presents as a bright red polyp or fleshy nodule, 0.5–2 cm in diameter;⁷⁸ it may discharge a mucoid secretion. A distinctive umbilical polyp, devoid of any epithelial component and termed a fibrous umbilical polyp, is discussed further later.

Urachal anomalies usually present at or soon after birth.⁷⁴ They may present as periumbilical dermatitis.⁷⁹ A patent urachus will result in the passage of urine from the umbilicus. Urachal sinuses and deeper cysts result from partial obliteration of the urachus, with small persistent areas.⁸⁰

Other lesions presenting at the umbilicus include endometriosis (see p. 526), primary⁸¹ and secondary tumors (see p. 1118),⁸² and inflammatory granulomas.⁸³ Umbilical endometriosis with a urachal remnant has been reported.⁸⁴ The granulomas result from inflammatory changes associated with persistent epithelialized tracts or simply from accumulation of debris in a deep umbilicus with resulting ulceration and inflammation.⁷⁴ Sometimes a pilonidal sinus is present.⁸⁵

The **fibrous umbilical polyp** appears to be a distinctive lesion of early childhood with an uncertain pathogenesis.⁸⁶ It has a marked predilection for boys. A series of 19 cases from one institution suggests that it is not rare. They ranged in size from 0.4 to 1.2 cm in diameter.

Histopathology

Umbilical (omphalomesenteric duct) polyps are covered by epithelium that is usually of small bowel or colonic type but occasionally of gastric type. Ectopic pancreatic tissue has also been described.⁷⁶ There is usually an abrupt transition from epidermis to the intestinal or gastric type of epithelium. Urachal remnants are lined by transitional epithelium;⁷⁴ sometimes smooth muscle bundles are present in their

wall. There may be a mild inflammatory cell infiltrate both in umbilical polyps and in urachal remnants.

Umbilical granulomas show variable inflammatory changes ranging from abscess formation to granulomatous areas.⁷⁴ Sometimes hair shafts or debris are present with associated foreign body giant cells. There is variable fibrosis.

The **fibrous umbilical polyp** is a dome-shaped lesion with a stromal proliferation of moderately cellular fibrous tissue without significant inflammation.⁸⁶ Fibroblastic cells are plump to elongate with abundant pale pink cytoplasm. Some cells show enlarged stellate nuclei or a ganglion cell appearance. Collagen is sparse to moderate in amount. The overlying epidermis shows a loss of rete ridges and basket-weave hyperkeratosis. Some cases show focal staining for muscle-specific actin and desmin but no staining for cytokeratin, CD34, S100, or epithelial membrane antigen.⁸⁶

Primary tumors of the umbilicus may take the form of adenocarcinoma, sarcoma, melanoma, squamous cell carcinoma, or, rarely, basal cell carcinoma.⁸² Rarely, umbilical adenocarcinomas assume a papillary pattern with psammoma bodies.⁸⁷ A clear cell acanthoma-like lesion of the umbilicus has been reported in an infant.⁸⁸ In a large series from Duke University, the most common primary umbilical malignancy was melanoma, with the remainder consisting of basal cell carcinoma and squamous cell carcinoma. Among those with metastases in the umbilical region, 85% derived from a known primary, the most common being ovarian, endometrial, and pancreatobiliary in women and genitourinary, pancreatobiliary, and gastrointestinal in men. In 15% of patients, a primary tumor site was not assigned; the majority of these were poorly differentiated carcinomas or adenocarcinomas, but also included were signet ring cell adenocarcinoma and neuroendocrine tumors.⁸⁹

RELAPSING POLYCHONDritis

Relapsing polychondritis is a rare multisystem disorder of unknown etiology manifesting with recurrent inflammation of the cartilaginous tissues of different organs, particularly the ear, but also the nasal septum and tracheobronchial cartilage.⁹⁰⁻⁹⁴ A frequent presentation is with tenderness and reddening of one or both ears resembling an infectious cellulitis.⁹⁵⁻⁹⁷ Onset is usually in middle age. Pediatric cases are uncommon.⁹⁸ Other manifestations include polyarthritides, ocular inflammation, audiovestibular damage, cardiac lesions, and a vasculitis.^{90,99,100} Relapsing polychondritis has been reported in association with psoriasis,¹⁰¹ psoriasis and alopecia areata,¹⁰² erythema multiforme,¹⁰³ aseptic abscesses,¹⁰⁴ myelodysplastic syndromes,^{105,106} malignant lymphoma,^{107,108} acute febrile neutrophilic dermatosis (Sweet's syndrome),^{109,110} HIV infection,¹¹¹ and, in one case, pseudocyst of the auricle.¹¹² The concurrence of Sweet's syndrome and relapsing polychondritis has been associated with hematological malignancy, although not invariably;¹¹⁰ there are two recent reports of these conditions in patients with myelodysplastic syndrome.^{113,114} There is also an association between relapsing polychondritis with fixed papular and annular urticarial lesions and myelodysplastic syndrome.¹¹⁵ Its association with Behçet's disease has been called 'MAGIC syndrome' (*mouth and genital ulcers with inflamed cartilage*).¹¹⁶ Relapsing polychondritis needs to be distinguished from Wegener's granulomatosis.¹¹⁷ The course of the disease is variable, but there is usually progressive destruction of cartilage, with consequent deformities. Death ensues in up to 25% of patients as a result of respiratory and cardiovascular complications.

There are pointers to an immunological pathogenesis. These include the detection of cell-mediated immunity to cartilage, the presence of antibodies to type II collagen,¹¹⁸ and the demonstration by direct immunofluorescence of immunoglobulins and C3 in the chondrofibrous junction and around chondrocytes.^{112,119} A case thought to have

been precipitated by the use of the drug goserelin (Zoladex®) for the treatment of prostatic adenocarcinoma has been reported.¹²⁰

Colchicine,^{121,122} dapsone,^{123,124} and corticosteroids have been used in management. The efficacy of biologic agents, particularly tumor necrosis factor- α blockers, has not been determined with certainty, partly due to the absence of randomized controlled trials and different treatment end points used in the various existing publications.¹²⁵

The Relapsing Polychondritis Disease Activity Index has recently been developed and validated.¹²⁶

Histopathology⁹⁰

The initial changes are a decrease in the basophilia of the involved cartilage, degeneration of marginal chondrocytes which become vacuolated with pyknotic nuclei, and a florid perichondritis with obscuring of the chondrofibrinous interface (Fig. 19.4). The inflammatory cell infiltrate initially contains many neutrophils, but there are progressively more lymphocytes, plasma cells, and histiocytes in the infiltrate, with occasional eosinophils. A vasculitic component is sometimes present.

Figure 19.4 Relapsing polychondritis. (A) Low-power view of ear cartilage. The decrease in basophilia is apparent. (B) There is degeneration of marginal chondrocytes, some showing focal vacuolization and pyknotic nuclei. An inflammatory infiltrate obscures the chondrofibrinous interface. (H&E)

With time, there is derangement of the cartilaginous matrix and its replacement by fibrous tissue.¹²⁷ Calcification and even metaplastic bone may develop in the late stages when only a scattering of chronic inflammatory cells remain. The cutaneous fixed papular and annular urticarial lesions show evidence for lymphocytic vasculitis, with endothelial swelling, focal fibrin deposits, and an infiltrate composed mainly of lymphocytes, with a few neutrophils and erythrocyte extravasation – features consistent with lymphocytic vasculitis. These changes are seen in and around small vessels in the papillary and mid dermis; direct immunofluorescence findings are negative.¹¹⁵

Electron microscopy

A large number of dense granules and vesicles, compatible with matrix vesicles or lysosomes, surround the affected chondrocytes.¹²⁸

ACANTHOSIS NIGRICANS

Acanthosis nigricans is a cutaneous manifestation of a diverse group of diseases that include internal cancers and various endocrine and congenital syndromes (Table 19.1).^{129–132} It may occur as an inherited disorder and in association with Down syndrome.¹³³ It may also be related to the ingestion of certain drugs. In all these circumstances, acanthosis nigricans presents as symmetrical, pigmented, velvety plaques and verrucous excrescences confined usually to the flexural areas of the body, particularly the axillae.^{129,130} It may also involve the back of the neck, the periumbilical and anogenital regions, and the face.^{134–136} Rarely, there is generalized involvement of the skin.^{137–140} The oral mucosa, particularly that of the lips and tongue, is also affected in 25% or more of cases.¹⁴¹ Involvement of the esophagus has been reported.¹⁴² Hyperkeratotic lesions may develop on the palms, soles, and knuckles.^{143–145} The palmar lesions are sometimes referred to as **tripe palms**. Such cases should be distinguished from the condition called **acral acanthotic anomaly** or acral acanthosis nigricans, in which velvety, hyperpigmented plaques occur on the elbows, knees, knuckles, and the dorsal surfaces of both feet in individuals with a dark complexion.^{146,147} A unilateral nevoid form has been described.¹⁴⁸

The *paraneoplastic type* of acanthosis nigricans is a rare manifestation of an internal cancer, usually an adenocarcinoma of the stomach or other part of the alimentary tract.^{149–155} Lymphomas,¹⁵⁶ renal carcinoma,¹⁵⁷ endometrioid carcinoma of the parametrium,¹⁵⁸ ovarian carcinoma,¹⁵⁹ lung carcinoma,¹⁶⁰ bladder carcinoma,¹⁶¹ liver tumors,¹⁶² and squamous cell carcinomas¹⁶³ are occasionally associated. Acanthosis nigricans may precede or follow the diagnosis of the cancer, but in most instances the two are diagnosed simultaneously.^{150,158,164} The sign of Leser-Trélat, another paraneoplastic phenomenon, may occur in

Table 19.1 Clinical associations of acanthosis nigricans

Paraneoplastic

Carcinomas of alimentary tract, liver, kidney, bladder, lung, cervix, and lymphomas

Endocrine and congenital

Insulin resistance syndrome, hyperinsulinemia, lipoatrophy, obesity, Prader-Willi syndrome, leprechaunism, pineal hyperplasia

Familial

Inherited disorder, Down syndrome, ectodermal dysplasia (Lelis' syndrome), SADDAN, and Crouzon syndromes, *FGFR3* mutations

Drugs

Somatotropin, corticosteroids, oral contraceptives, diethylstilbestrol (stilbestrol), methyltestosterone, niacin (nicotinic acid), triazinate, gemfibrozil, amprenavir, palifermin, topical fusidic acid

SADDAN, severe achondroplasia with developmental delay and acanthosis nigricans.

association with acanthosis nigricans.¹⁵⁵ Florid cutaneous papillomatosis may also accompany this variant of acanthosis nigricans.¹⁶⁵ There are reports of the reversibility of the skin lesions upon removal or treatment of the accompanying malignant disease.^{150,164}

The various *endocrine disorders* and *congenital syndromes* that may be complicated by acanthosis nigricans appear to have in common a resistance of the tissues to the action of insulin,^{132,166–174} hyperinsulinemia may be present.^{175,176} Acanthosis nigricans has been reported in the very rare Alstrom syndrome (OMIM 203800), an autosomal recessive disorder characterized by hyperinsulinemia, obesity, type 2 diabetes mellitus, progressive cone-rod dystrophy leading to blindness, and sensorineural hearing loss.¹⁷⁷ Insulin resistance is present in the case of lipotrophy (lipodystrophy),^{178–182} the Prader-Willi syndrome,¹⁸³ leprechaunism,¹⁷⁹ pineal hyperplasia, and the so-called ‘type A and B insulin resistance syndromes’ (Rabson-Mendenhall syndrome; OMIM 262190).^{166,167,184–186} Obesity is often present.^{187,188} Acanthosis nigricans has been found in 19, 23, and 4% of African American, Hispanic, and non-Hispanic white youths, respectively, who have a body mass index ≥ 98 th percentile.¹⁸⁹ Alterations in leptin levels have also been implicated.^{146,182} A combination of acanthosis nigricans and insulin resistance is found in approximately 5% of hyperandrogenic females, often in association with polycystic ovaries.^{167,170,190,191} Acanthosis nigricans localized to a plaque of scleredema has been reported in a diabetic patient.¹⁹² Its occurrence in pregnancy, not complicated by diabetes mellitus, is difficult to explain.¹⁹³

Onset of the rare *familial cases* is in early childhood.^{194–196} There may be accentuation of symptoms at puberty. This variant is inherited as an autosomal dominant trait, although there may be variable phenotypic expression.¹⁹⁴ The association of acanthosis nigricans with ectodermal dysplasia has been called Lelis’ syndrome (OMIM 608290).¹⁹⁷ Other syndromes associated with acanthosis nigricans include the severe achondroplasia with developmental delay and acanthosis nigricans (SADDAN syndrome, thanatophoric dysplasia; OMIM 187600),¹⁹⁸ hypochondroplasia (OMIM 146000),¹⁹⁹ and Crouzon syndrome with acanthosis nigricans (OMIM 612247). They result from mutations in the fibroblast growth factor receptor 3 (*FGFR3*) gene on chromosome 4p16.3.^{200,201} Sometimes familial acanthosis nigricans occurs with mutations in this gene, but there are no associated dysmorphic features.²⁰² Rare cases, distributed along Blaschko’s lines, have variously been called nevoid acanthosis nigricans or epidermal nevus of the acanthosis nigricans type.²⁰³ In a series of four cases, the presence of typical acanthosis nigricans elsewhere in one case suggests the possibility that the unilateral component along Blaschko’s line may be an example of type 2 mosaicism.²⁰⁴ Of further interest is the finding that a large proportion of epidermal nevi are caused by mutations in the gene controlling activating fibroblast growth factor receptor 3 (*FGFR3*) in the epidermis,²⁰⁵ a finding also made in some cases of acanthosis nigricans (discussed previously) and in some seborrheic keratoses.²⁰⁶

Drugs that have been incriminated in the causation of acanthosis nigricans include somatotropin,²⁰⁷ corticosteroids,²⁰⁸ niacin (nicotinic acid),^{209,210} oral contraceptives, diethylstilbestrol (stilbestrol), the folic acid antagonist triazine,²¹¹ gemfibrozil, amprenavir,²¹² the human recombinant keratinocyte growth factor palifermin,^{213,214} and methyltestosterone.²¹⁵ Acanthosis nigricans-like lesions have developed in ichthyotic skin following the topical application of fusidic acid.²¹⁶ Its occurrence at the site of repeated insulin injections is rare.²¹⁷

The molecular basis of acanthosis nigricans is becoming increasingly clear; it appears to represent an abnormal epidermal proliferation in response to various factors.^{181,218} Members of the tyrosine kinase receptor (TKR) superfamily, including epidermal growth factor receptor (EGFR), insulin growth factor receptor 1 (IGFR1), and fibroblast growth factor receptors (FGFRs), particularly *FGFR3*, are some of the factors involved.²¹⁸ They have both mitogenic and antiapoptotic effects on keratinocytes. In the case of the paraneoplastic group, the factor may be a tumor-produced peptide, such as epidermal growth factor

(EGF) or transforming growth factor (*TGF- α*),^{160,219} whereas in the group related to tissue insulin resistance, the tissue growth factors include insulin itself, which may be increased in some of these conditions.^{170,181,220} However, the occurrence of acanthosis nigricans is not invariable at any given level of insulin resistance (based on the homeostatic model assessment for insulin resistance – HOMA-IR), and therefore other factors may be involved in this population of patients. With this in mind, studies of Galhardo *et al.* have found elevated levels of pigment epithelium-derived factor, a member of the serine protease inhibitor supergene family, among those who develop acanthosis nigricans.²²¹ Alterations in insulin growth factor receptors also occur.²¹⁸ There is also evidence that abnormalities of the insulin receptor pathway are involved in children with pre- and co-obese acanthosis nigricans, specifically with regard to the frequency of the T allele of *INSR* His1085His genotypes compared to normal controls.²²² The characteristic flexural localization remains an enigma. The rare keratins, 18 and 19, have been reported in basal keratinocytes in acanthosis nigricans.²²³

Histopathology

There is hyperkeratosis and papillomatosis but only mild acanthosis (Fig. 19.5).¹³⁰ The papillomatosis results from the upward projection of

Figure 19.5 (A) Acanthosis nigricans. (B) The papillomatosis and intervening ‘valleys’ are conspicuous in this case. (H&E)

Figure 19.6 Acanthosis nigricans. (A) This biopsy taken from the axilla shows a less regular appearance than the previous case. (B) Another atypical case illustrating the variability that this condition can show. (H&E)

finger-like dermal papillae that are covered by thinned epidermis.¹⁴¹ In the 'valleys' between these papillary projections, the epithelium shows mild acanthosis with overlying hyperkeratosis (Fig. 19.6).¹⁴¹ There may be some hyperpigmentation of the basal layer, but the pigmentation of the lesions noted clinically results largely from the hyperkeratosis. In some instances, there is hypertrophy of all layers of the epidermis

and the pattern resembles that seen in epidermal nevi (discussed previously). A resemblance to seborrheic keratoses has been noted in some cases. There is usually no dermal inflammation. There is a close histological resemblance to the lesions of confluent and reticulated papillomatosis (see later).

Oral lesions differ from the cutaneous ones by showing marked thickening of the epithelium with papillary hyperplasia and acanthosis.¹⁴¹ There is a superficial resemblance to the lesions of condyloma acuminatum. There is usually mild chronic inflammation in the submucosal tissues.¹⁴¹

Finally, it is worth noting that a pattern resembling acanthosis nigricans has been reported at the site of repeated insulin injections.²²⁴

Differential diagnosis

Although the microscopic features of acanthosis nigricans are characteristic, they are not entirely specific. Similar combinations of hyperkeratosis and papillomatosis can be seen in confluent and reticulated papillomatosis (see later), some seborrheic keratoses, and epidermal nevi. Seborrheic keratoses may also have horn cysts and often display a greater degree of acanthosis, whereas the changes in confluent and reticulated papillomatosis are generally less pronounced than those in acanthosis nigricans. Idiopathic eruptive macular pigmentation looks quite different clinically from acanthosis nigricans, given the size of the lesions and their anatomic distribution, but microscopically the changes can be identical to those of acanthosis nigricans.²²⁵ A similar condition, consisting of an eruption of well-demarcated, polycyclic to linear, velvety, hyperpigmented lesions, has been reported in children and young adults in the absence of associated factors normally linked with acanthosis nigricans; such lesions have been termed 'nevroid acanthosis nigricans' and, more recently, RAVEN (*rounded and velvety epidermal nevus*).²²⁶ Forms of reticulated hyperpigmentation (Dowling–Degos or Galli–Galli disease, reticulated acropigmentation of Kitamura) lack the papillomatosis of acanthosis nigricans. The same can be said of solar lentigines, although lesions showing evidence for evolution to seborrheic keratosis may develop a mild degree of papillomatosis. Clinical history and physical examination findings obviously have a significant bearing on the diagnosis in many cases. However, once a diagnosis of acanthosis nigricans is established, there is still a need to determine the underlying cause. In the absence of a family history, associated features of ectodermal dysplasia, an endocrinologic disorder, or relevant medication history, the onset of acanthosis nigricans in an adult should prompt a search for malignancy, particularly of the gastrointestinal tract.

CONFLUENT AND RETICULATED PAPILLOMATOSIS

Confluent and reticulated papillomatosis (of Gougerot and Carteaud) is a rare form of papillomatosis characterized by the development of asymptomatic, small red to brown, slightly verrucous papules with a tendency to central confluence and a reticulate pattern peripherally.^{227–230} Uncommonly, the lesions are nonpigmented with a fine white scale.²³¹ Pruritus has been reported.²³² It involves particularly the upper part of the chest and the intermammary region and back; the neck, chin, upper parts of the arms, and the axillae may also be involved. It has a predilection for younger individuals, with the mean age of onset of 15 years in one series of 39 patients.²³³ Familial occurrence has been documented.^{234–236}

It has been regarded as a variant of acanthosis nigricans, as a genodermatosis, as an unusual response to ultraviolet light²³⁷ or to *Pityrosporum orbiculare* infection,^{238–241} and as a result of some unidentified endocrine imbalance.^{227,242} A case has been reported in association with hyperthyroidism²⁴³ and with the partial 15q tetrasomy syndrome.²⁴⁴ In 2005, a previously unknown *Dietzia* strain (an

actinomycete) was isolated from the skin scrapings of a case.²⁴⁵ This remains to be confirmed. Its coexistence with acanthosis nigricans has been reported.²⁴⁶

Response to calcipotriene (calcipotriol)^{247,248} and retinoids^{249,250} favors the theory that it is an abnormality of keratinization. On the other hand, response to various antibiotics, particularly minocycline, has also been reported.^{233,251–259} Minocycline is now the treatment of choice. It has also been successfully treated with topical mupirocin ointment.²⁶⁰

Histopathology^{227,261}

The epidermis is undulating with hyperkeratosis, low papillomatosis, and some acanthotic downgrowths from the bases of the 'valleys' between the papillomatous areas (Fig. 19.7). Papillomatosis may be absent or subtle in early or late lesions of this condition, but it has been suggested that the presence of basket-weave hyperkeratosis invaginating through the epidermis may be a 'clue' in such cases.²⁶² There may also be mild basal hyperpigmentation and focal atrophy of the malpighian layer. These changes resemble acanthosis nigricans,²⁶³ although they are not usually as well developed as in this condition (Fig. 19.8). However, there may be mild dilatation of superficial dermal blood vessels and sometimes beading of elastic fibers – changes not usually attributed to acanthosis nigricans.

Figure 19.7 (A) Confluent and reticulated papillomatosis with papilloma formation. (B) The epidermis is undulating with acanthosis. (H&E)

Some cases have a resemblance to seborrheic keratosis, but the interface between the adjacent normal skin and lesional skin is better defined in seborrheic keratosis.²⁶⁴

Electron microscopy

There is an alteration of cornified cell structures and an increase in the number of Odland bodies in the granular layer.^{261,265}

ACROKERATOSIS PARANEOPLASTICA

Acrokeratosis paraneoplastica (Bazex's syndrome) is a rare paraneoplastic dermatosis associated with cancers that are usually supradiaphragmatic.^{266–271} in origin, although tumors at other sites have also been incriminated.^{272,273} Sarcomas and lymphomas have also been implicated in the etiology.^{274,275} It commences with violaceous erythema and psoriasiform scaling on the hands and feet with later extension to the ears and nose.^{276,277} Violaceous keratoderma of the hands and feet develops, and ill-defined psoriasiform lesions eventually form at other sites on the arms and legs.²⁶⁷ Bullous lesions are rare.²⁷⁸ Coexistence with papuloerythroderma of Ofuji has been reported.²⁷⁹ These changes in the skin usually precede the onset of symptoms related to the associated cancer.^{280–282} Removal of the neoplasm leads to a remission of the condition in 95% of cases, and recurrence triggers a relapse.²⁷⁵ This syndrome has been reported in association with acquired ichthyosis, another paraneoplastic disorder.²⁸³ The pathogenesis of the condition is unknown, although TGF- α , produced by tumor cells, may play a role.²⁸³

Histopathology²⁸⁰

The changes are somewhat variable and not diagnostically specific. There is hyperkeratosis, focal parakeratosis, and acanthosis that may be psoriasiform or mild and irregular in format. Variable epidermal changes include spongiosis with associated exocytosis of lymphocytes, basal vacuolar change, and scattered apoptotic keratinocytes at all levels of the epidermis.^{266,267} Rarely, intraepidermal or subepidermal blisters have occurred.²⁸⁴ There is a mild perivascular lymphocytic infiltrate in the papillary dermis. Another report described a superficial and deep perivascular and periadnexal lymphocytic infiltrate.²⁸⁵ Fibrinoid degeneration of small vessels and scattered 'pyknotic' neutrophils have been described in some reports but specifically excluded in others.^{266,280,286} In one case subjected to direct immunofluorescence

Figure 19.8 Another case of confluent and reticulated papillomatosis with less papillomatosis. (H&E)

study, linear IgG and C3 deposition were found along the dermal-epidermal junction – a configuration reminiscent of pemphigoid despite the absence of blistering.²⁸⁷ An epitope spreading phenomenon may have been at work in that case.

ERYTHRODERMA

Erythroderma (exfoliative dermatitis) is a cutaneous reaction pattern that can occur in a wide variety of benign and malignant diseases.^{18,288–290} It is uncommon, with an incidence of 1 or 2 per 100,000 of the population.^{288,291} Clinically, it is characterized by erythema and exfoliation that involve all or most of the skin surface.²⁸⁹ Distressing pruritus is often present.²⁸⁸ Other clinical features include fever, malaise, keratoderma, alopecia, and a mild, generalized lymphadenopathy. Laboratory findings include blood eosinophilia, elevated levels of IgE, and, in some, a polyclonal gammopathy.^{288,292} The mean age at onset is approximately 60 years, although cases in infancy, often associated with ichthyosiform dermatoses (see p. 286) or immunodeficiency, have been reported.^{293–297} Omenn's syndrome (OMIM 603554) combines erythroderma and combined immunodeficiency.²⁹⁸ There is a male predominance, particularly in the idiopathic group (see later).

Erythroderma is most often seen as an exacerbation of a pre-existing dermatological condition, but it may also be drug related or be associated with cutaneous T-cell lymphoma or some other malignant tumors. Approximately 15% of cases are idiopathic (Table 19.2). In one retrospective study, 62.5% were related to an underlying dermatosis, 16% were due to drug reactions, and 12.5% were due to cutaneous T-cell lymphoma.²⁹⁹ In a recent study, there was a pre-existing dermatosis in 74.4%, 14.6% were idiopathic, and drugs and malignancy each accounted for 5.5% of cases.³⁰⁰ In a Chinese study of erythroderma, pre-existing dermatoses were involved in 72% of cases (psoriasis being most common), drugs in 17%, and malignancy in 4.9%; 6.1% of cases were idiopathic.³⁰¹ In this report, Chinese herbal medicines were most frequent in the drug-induced category. Less usual causes of erythroderma were hypereosinophilic syndrome, sarcoidosis, and dermatomyositis.³⁰¹

A pre-existing dermatosis is present in more than 50% of cases.²⁹¹ Psoriasis is the most common of these.^{302–304} Various factors, including the use of systemic steroid therapy or retinoids, have been incriminated in precipitating an erythrodermic crisis in psoriasis.^{302,305} Other underlying dermatoses include atopic dermatitis, seborrheic dermatitis, allergic contact dermatitis, photosensitivity syndromes, pityriasis rubra pilaris, and, rarely, stasis dermatitis, dermatophytosis, pemphigus foliaceus, and even bullous pemphigoid.^{300,307–310} In some

countries, there is a significant association with HIV infection,³¹¹ in contrast, pulmonary tuberculosis is a very rare association.³¹²

Drug-induced cases may follow topical sensitization to neomycin, ethylenediamine, or clioquinol (Vioform®).³¹³ Usually, erythroderma follows the ingestion of a drug such as phenytoin, penicillin, isoniazid, trimethoprim and sulfonamides, antimalarials,³¹⁴ thiazide diuretics, gold, chlorpromazine, calcium carbimide (cyanamide),³¹⁵ nifedipine,³¹⁶ roxatidine,³¹⁷ escitalopram,³¹⁸ imatinib,³¹⁹ or allopurinol.^{307,320} There are a few case reports of erythroderma following the use of certain non-steroidal anti-inflammatory drugs, such as sulindac, meclofenamate sodium, and phenylbutazone,³²¹ and individual case reports of cases caused by morphine sulfate³²² and adalimumab.³²³ One case followed the use of β -blocker eye drops (timolol maleate),³²⁴ and another followed the use of hypericum (St John's wort).³²⁵ Erythroderma as a photoallergic reaction to doxycycline occurred in the course of treatment of erythema chronicum migrans.³²⁶ The use of recombinant cytokine therapy may precipitate erythroderma (see p. 608).^{327,328} Drug-related cases usually have a rapid onset and relatively quick resolution over 2–6 weeks, in contrast to the more prolonged course of the idiopathic and lymphoma-related cases.³⁰⁷ Erythroderma due to latex-producing plants has been reported.³²⁹

Approximately 10% of cases are associated with a cutaneous T-cell lymphoma, in the form of the Sézary syndrome or erythrodermic mycosis fungoides.³³⁰ The erythroderma may precede or occur concurrently with the diagnosis of the cancer.^{289,331} Uncommonly, erythroderma is associated with an extracutaneous lymphoma or some other tumor.^{332–334}

The idiopathic group, also known as 'the red man syndrome', is associated more often with keratoderma and dermatopathic lymphadenitis than the other groups.³³⁵ It is also more likely to persist than some of the other types. Some cases may progress to mycosis fungoides after many years.^{335,336}

The pathogenetic mechanisms involved in erythroderma are not known. The erythema results from vascular dilatation and proliferation, and it has been suggested that interactions between lymphocytes and endothelium may play a role.³³⁷ Circulating adhesion molecules are detectable in erythroderma, but their values are not of differential diagnostic use.³³⁸ A lymphocytopenia involving CD4⁺ T cells is sometimes found, probably a consequence of the sequestration of these cells in the skin.³³⁹

Histopathology³⁴⁰

Skin biopsies in erythroderma have been regarded as 'largely unrewarding',³²⁰ 'of variable usefulness',³⁰⁷ 'of little value',³⁴¹ and 'misleading'.³⁴¹ However, in one series, an etiological diagnosis was made on the skin biopsy in 53% of cases,³⁴² and in another series, it was made in 66% of cases.³⁴³ (Fig. 19.9). In this latter series, it was found that diagnostic histopathological features of the underlying disease were retained in the majority of cases.³⁴³ The diagnostic accuracy increases if multiple biopsies are taken simultaneously.³⁴² Biopsies are most often diagnostic in erythroderma associated with cutaneous T-cell lymphoma and, to a lesser extent, psoriasis and spongiotic dermatitis.³⁴² Nevertheless, one-third of biopsies from patients with established erythrodermic cutaneous T-cell lymphoma are nondiagnostic.³⁴⁴ In these cases, an aberrant T-cell immunophenotype may be found; a clonal population of T cells is usually present.^{344,345}

Usually, there is variable parakeratosis and hypogranulosis. The epidermis shows moderate acanthosis, and at times, there is psoriasiform hyperplasia, but this finding does not always correlate with the presence of underlying psoriasis.³⁴¹ Mild spongiosis is quite common even when there is underlying psoriasis. Other features of psoriatic erythroderma resemble those seen in early lesions of psoriasis with only mild epidermal hyperplasia, mounds of parakeratosis with few neutrophils, and red cell extravasation in the papillary dermis.³⁴⁶ Blood

Table 19.2 Etiologies of erythroderma

Pre-existing dermatosis

Psoriasis, atopic dermatitis, seborrheic dermatitis, allergic contact dermatitis, photosensitivity syndromes, pityriasis rubra pilaris, stasis dermatitis, pemphigus foliaceus, bullous pemphigoid, HIV infection

Drugs

Phenytoin, penicillin, isoniazid, trimethoprim, sulfonamides, antimalarials, thiazides, gold, chlorpromazine, calcium carbimide (cyanamide), nifedipine, roxatidine, imatinib, allopurinol, NSAIDs, timolol maleate eye drops, hypericum (St John's wort), recombinant cytokines, morphine sulfate, adalimumab

Lymphoma

Cutaneous T-cell lymphoma (mycosis fungoides and Sézary syndrome), extracutaneous lymphoma, rarely with solid tumors

Idiopathic

Figure 19.9 Erythroderma. In this case of atopic dermatitis, there is little spongiosis. The epidermal thickening with only mild psoriasiform folding is a feature of atopic dermatitis. (H&E)

Figure 19.10 Papuloerythroderma. This example shows parakeratosis, acanthosis, and slight spongiosis. There is a loosely organized, superficial dermal perivascular infiltrate composed mainly of lymphocytes. (H&E)

vessels in the upper dermis are usually dilated, and sometimes there is endothelial swelling.³⁴⁰

There is a moderately heavy chronic inflammatory cell infiltrate in the upper dermis: this is sometimes perivascular in distribution and at other times more diffuse.³⁴⁷ Atypical cells with cerebriform nuclei are present in the infiltrate in cases of erythroderma related to cutaneous T-cell lymphomas. Eosinophils may be present in the infiltrate, and occasionally they are plentiful.³⁴⁸ Exocytosis of lymphocytes is a frequent finding.

Drug-related cases may sometimes simulate the picture of mycosis fungoides, with prominent exocytosis and scattered atypical cells with cerebriform nuclei in the infiltrate.³⁴⁸ In contrast to mycosis fungoides, however, Pautrier microabscesses are not present in the benign erythrodermas. Eosinophils are not always present in drug-related cases, as might be expected.³⁴⁸ A very occasional apoptotic keratinocyte may be a clue to the drug etiology. Rarely, the picture is frankly lichenoid in type.^{316,349}

Electron microscopy

One study showed a close association between lymphocytes and endothelial cells, although the significance of this finding remains to be evaluated.³³⁷ Some lymphocytes were described as showing 'blastoid' transformation.³³⁷

Differential diagnosis

In a recent study of 47 biopsies from 45 adult patients with erythroderma, a correct differential diagnosis of lymphoma versus erythrodermic inflammatory dermatosis was obtained in 57% of cases, although among all diagnoses a specific, correct diagnosis was made in only 31% of cases.³⁵⁰ The most helpful features in recognizing lymphoma versus nonlymphoma were Pautrier microabscesses, atypical lymphocytes, and a dense dermal infiltrate. Of two new immunohistochemical markers of Sézary syndrome usable in paraffin-embedded tissues, β -catenin was not useful in distinguishing erythrodermic T-cell lymphoma from erythrodermic inflammatory dermatoses, whereas JunB was a specific marker for lymphoma but not sufficiently sensitive.³⁵⁰ Clinically, it is also important when faced with a case of erythroderma, particularly one unresponsive to initial therapies, to consider the possibility of Norwegian scabies; skin scrapings and/or biopsy search for mites and their products could be useful in such circumstances.³⁵¹

PAPULOERYTHRODERMA

Papuloerythroderma of Ofuji is a rare entity, first reported from Japan, featuring widespread erythematous, flat-topped papules with a striking sparing of body folds (the so-called 'deck-chair' sign).³⁵²⁻³⁵⁵ Eosinophilia and lymphopenia are sometimes present. It occurs most commonly in elderly males. It is often associated with underlying lymphoma or cancer.³⁵⁶⁻³⁵⁸ It has developed in patients with atopic erythroderma,³⁵⁹ HIV infection,³⁶⁰ hepatitis C infection,³⁶¹ and in one with biliary sepsis.³⁶² Aspirin and furosemide (frusemide) have also been suggested as precipitants.^{363,364} Papuloerythroderma appears to be a distinct clinical entity, but its etiology is unknown. It has been suggested that it may be an early variant of mycosis fungoides.³⁶⁵⁻³⁷⁰ Most cases run a chronic course. Several treatment regimens have been used with varying success.³⁷¹

Histopathology

The epidermis is usually normal, although it may show slight acanthosis, spongiosis, and parakeratosis. There is a dense, predominantly perivascular infiltrate of lymphocytes, plasma cells, and eosinophils in the upper and mid dermis (Fig. 19.10). In another recent study of two cases and a review of the literature, plasma cells, neutrophils, and multinucleated giant cells were seldom encountered in dermal inflammatory infiltrates.³⁷²

S100-positive dendritic cells are abundant in the dermis.³⁵⁴

SCALP DYSESTHESIA

Scalp dysesthesia is characterized by symptoms of burning, stinging, or itching, which is often associated with psychological stress. In a recent study, 14 of 15 patients with scalp dysesthesia were found to have cervical spine abnormalities, most of which represented degenerative disk disease at C5–C6; some patients received symptomatic relief from gabapentin.³⁷³ The author has received biopsies (all normal) from at least 10 cases and coined the term 'burning scalp syndrome'. Sometimes telogen effluvium may accompany this condition. Patients have benefited from low-dose antidepressants.³⁷⁴

CUTANEOUS EMPHYSEMA

Cutaneous and soft tissue emphysema is rarely encountered in clinical dermatology.³⁷⁵ It may follow head and neck surgery, including various dental treatments, trauma, cutaneous cryotherapy,^{376,377} intermittent positive pressure ventilation, and lung disease associated with alveolar rupture.³⁷⁵ It is usually confined to the cervicofacial region, but involvement of the elbow region has been described.³⁷⁸ Cutaneous emphysema manifesting as swelling and pseudovesicles of the eyelids resulted from perforation of the trachea following orotracheal intubation.³⁷⁹ Clinically, it is most often confused with angioedema.³⁷⁵ It resolves in a few days.

Histopathology

Collagen bundles in the dermis are attenuated and separated by clear spaces. There are no mucin deposits or inflammation. Adipose tissue has been reported to show 'fragmentation of cell membranes'.³⁷⁵

Cutaneous drug reactions

Introduction	596	Offending drugs	604	Retinoids	605
Clinicopathological reactions	597	Antibiotics	604	Cytotoxic drugs	606
Exanthematous drug reactions	598	Nonsteroidal anti-inflammatory drugs	605	Recombinant cytokines	608
Halogenodermas	599	Psychotropic drugs	605	Intravenous immunoglobulin	610
Drug hypersensitivity syndrome (drug rash with eosinophilia and systemic symptoms (DRESS) syndrome)	600	Phenytoin sodium and anticonvulsants	605	Monoclonal antibodies	610
Other clinicopathological reactions	601	Gold	605	Protease inhibitors	610
		Macrolactams (calcineurin inhibitors)	605	Botulinum toxin	610
